

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

A TREATISE
ON THE
PRINCIPLES AND PRACTICE
OF
MEDICINE;

DESIGNED FOR THE USE OF
PRACTITIONERS AND STUDENTS OF MEDICINE.

BY
AUSTIN FLINT, M.D., LL.D.,
LATE PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE
IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK, ETC.

SEVENTH EDITION,
THOROUGHLY REVISED

BY
FREDERICK P. HENRY, A.M., M.D.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE WOMAN'S MEDICAL COLLEGE
OF PENNSYLVANIA; PHYSICIAN TO THE PHILADELPHIA HOSPITAL; CORRESPONDING
MEMBER OF THE ROYAL ACADEMY OF MEDICINE OF ROME, ETC.

PHILADELPHIA:
LEA BROTHERS & CO.

1894.

Entered according to Act of Congress, in the year 1894, by

Printer, Philada.

PREFACE.

IN the present edition of this work there is but one radical change—the omission of the section on General Pathology. This is in accordance with the practice of nearly all modern writers, especially those of the European Continent, who draw a strict line of demarcation between special and general pathology, as well as with that of the chief medical schools of the world, in which there are separate chairs for general pathology and the practice of medicine, or special pathology. Notwithstanding this omission, the book is scarcely reduced in size, for the other alterations have been almost entirely in the way of addition. The present editor has contributed about one hundred pages of new matter, in which are included more than twenty distinct articles, besides numerous interpolations in every section of the book. Among the new articles are those on Pulsating Pleurisy, Weil's Disease, Syringomyelia, Beri-beri, Hereditary Chorea, Acromegaly, Raynaud's Disease, Leprosy, Influenza, Lithæmia, Rickets, Actinomycosis, Anthrax, and Glanders. Chapter IV., on the Functional Diseases of the Stomach, has been very largely rewritten, and the article on Dyspepsia has been expunged. As remarked on page 373, the term dyspepsia is a "most serviceable cloak for ignorance, but has been worn threadbare and is about to be discarded." In place of the article on Dyspepsia are substituted articles on Nervous Vomiting, Peristaltic Unrest, Nervous Eructation, Merycismus, Incontinence of the Pylorus, Atony, Hyperacidity and Hypersecretion, and Nervous Dyspepsia, these various subjects being preceded by "introductory remarks" on the present methods of research in the diagnosis of gastric disease.

The classification of Flint has been practically retained, although, like all classifications of disease, it is open to criticism, and has caused the editor some little embarrassment. For example, the most suitable place that could be found for Leprosy was among the Eruptive Fevers. On consulting several recent text-books on medicine it was found that this difficulty had been solved by the omission of this important subject. It appears to the editor much better that it should be retained, even though its situation be not absolutely appropriate.

The last edition of this work appeared in 1886, the author being ably assisted in its revision by his son, Prof. Austin Flint, M. D., and by Prof. William H. Welch, M. D., of the Johns Hopkins University. The latter revised and in great part rewrote the descriptions of the anatomical characters of the various diseases considered in that edition, and also wrote the

articles or parts of articles relating to bacteriology. The alterations in this portion of the volume have not been numerous, but some have been indispensable. For example, Amœbic Dysentery and Amœbic Abscess of the Liver were unrecognized affections in 1886. Without entering into further details, it is believed that the following statement from the Preface to the fifth and sixth editions is still applicable, viz.: that the parts of the work relating to the anatomical characters of disease and to bacteriology "will serve as a digest of the essential facts pertaining to general and special pathological anatomy so far as this important branch of study bears upon practical medicine."

The revision of those parts of the book devoted to clinical history has been largely a work of supererogation, because the value of accurate descriptions of morbid phenomena is not impaired by time. In the department of clinical history Flint was unsurpassed, perhaps unrivalled.

Special attention has been given to the department of therapeutics, because it is the one in which the changes have been greatest. Among the multiplicity of new remedial agents discovered and advocated during the last eight years, a selection has been made of those which have withstood a thorough clinical test—the only one of value to the practitioner.

Whatever may be thought of the superstructure of this work, its foundations are imperishable. Some idea of their depth and breadth may be obtained from the following extract from the Preface to the last edition. It was written after the death of its distinguished author, by his son, Prof. Austin Flint: "The basis of the work is an unbroken series of records of cases in private practice and in hospitals, begun in 1833 and continued for more than half a century, covering sixteen thousand nine hundred and twenty-two folio pages of manuscript written with the author's own hand. These records embrace carefully-written histories of cases in all departments of practical medicine, observed under varied conditions of life, climate, and general surroundings. Soldiers in camp and barracks; the rich and the poor; those affected with diseases incident to lives of ease and luxury, and paupers in hospitals; the pioneers of Western New York and the inhabitants of the metropolis; patients in the wards of the almshouse and hospitals of Buffalo, of the Marine Hospital in Louisville, Kentucky, the great Charity Hospital in New Orleans, Louisiana, the Bellevue Hospital, the Charity Hospital, the dispensaries, and similar institutions in the city of New York; cases observed in the experience of a quarter of a century as a general practitioner, and of more than another quarter of a century as a consulting physician, including the epidemics which have occurred in this country within the last fifty years,—the experience derived from these various sources of observation, carefully recorded, studied, and analyzed, was finally used in the composition of this treatise, the first edition of which appeared in 1866. In the mean time the author's original contributions to practical medicine, embodied in special treatises, in communications published in medical periodicals, and in Transactions of med-

ical societies, have left their impress upon many departments which, in recent years, have been classed as specialties; although he was always a physician, never a specialist. A student of the history of practical medicine will often find observations and ideas, assumed to be of recent date, which had been anticipated by the author many years before. . . .

"Added to a literary training and a recorded experience almost without parallel was an exceptional knowledge and application of the best methods of teaching medicine, rendering the author one of the most popular and successful medical teachers of his time; a statement which will be echoed by thousands of practitioners, throughout this country and in foreign lands, who have attended his lectures. The lectures given by the author in 1885-86 completed his fiftieth regular course on the Principles and Practice of Medicine.

"Such, in brief, is the history of the author of this treatise as a practitioner, writer, and teacher."

The editor entered upon his task of revising this book with a feeling of reverence for the memory of its distinguished author, and, as a natural consequence, if he has erred, it has been in the direction of conservatism. He has constantly borne in mind the maxim, "Hold fast to that which is good," and in so doing has held fast to nearly all.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

Of the Different Aspects under which Individual Diseases are to be Considered in Treating of the Practice of Medicine, or Special Pathology; namely, Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention, and Treatment—Sense of the term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the terms Acute, Subacute, and Chronic—Symptoms or Events incidental to Diseases sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology—Nosological Arrangement adopted in this Work	PAGE 19
---	------------

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

ACUTE PLEURITIS.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory.—Acute Pleuritis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis	23
---	----

CHAPTER II.

ACUTE PLEURITIS (CONTINUED).

Treatment of Acute Pleuritis.—Measures indicated in the First Stage.—General Considerations relating to Bloodletting in Acute Inflammations.—The Use of Opium in Acute Pleuritis and other Acute Inflammations.—Measures indicated in the Second and Third Stages of Acute Pleuritis	32
--	----

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis: Anatomical Characters; Clinical History; Pathological Character; Causation; Prognosis; Diagnosis; Treatment; Thoracentesis.—Empyema, Pyo-	7
--	---

thorax, or Suppurative Pleuritis; Diagnosis; Prognosis; Treatment.—Pulsating Pleurisy.—Pleuritis with Pneumothorax, Pneumo-hydrothorax, Pneumo-pyothorax, or Pneumo-hæmothorax: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Pneumothorax.—Circumscribed Pleuritis.—Hydrothorax	PAGE 40
---	------------

CHAPTER IV.

PNEUMONITIS.

Seat of the Inflammation.—Varieties: Acute Lobar Pneumonitis: Anatomical Characters; Laws of the Disease; Clinical History; Causation; Diagnosis; Pathological Character; Prognosis	63
---	----

CHAPTER V.

PNEUMONITIS (CONTINUED).

Treatment of Acute Lobar Pneumonitis.—Lobar Pneumonitis in Children.—Lobular Pneumonitis.—Atelectasis.—Suppurative Pneumonitis.—Embolic Pneumonitis.—Abscess of the Lung.—Pneumonokoniosis, Anthracosis, etc.—Brown or Pigment Induration of the Lungs.—Hyperæmia of the Lungs.—Hypostatic Congestion.—Hypostatic Pneumonitis.—Pleurodynia and Dorso-Intercostal Neuralgia	80
--	----

CHAPTER VI.

PULMONARY PHTHISIS.

Anatomical Characters; Clinical History; Pathological Character; Causation.	99
---	----

CHAPTER VII.

PULMONARY PHTHISIS (CONTINUED).

Diagnosis; Prognosis; Treatment	115
---	-----

CHAPTER VIII.

Fibroid Phthisis.—Acute Miliary Tuberculosis.—General Tuberculosis	133
--	-----

CHAPTER IX.

BRONCHITIS.

Acute Bronchitis affecting the Large Bronchial Tubes: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Subacute Bronchitis.—Acute Bronchitis in Young Children.—Acute Bronchitis affecting the Small Bronchial Tubes.—Bronchitis with Fibrinous Exudation.—Circumscribed Bronchitis.—Chronic Bronchitis	138
---	-----

CHAPTER X.

EMPHYSEMA OF THE LUNGS.—ASTHMA.—PERTUSSIS.

Emphysema of the Lungs: Varieties; Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Asthma: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Pertussis, or Whooping Cough	154
--	-----

CHAPTER XI.

PULMONARY HEMORRHAGE.—PULMONARY GANGRENE.—PULMONARY ŒDEMA.—CARCINOMA.—HYDATIDS.

Pulmonary Hemorrhage.—Bronchorrhagia.—Pneumorrhagia.—Hemorrhagic Infarction.—Pulmonary Gangrene.—Pulmonary Œdema.—New Growths within the Chest.—Hydatids.—Syphilitic Disease of the Lungs	181
---	-----

CHAPTER XII.

DISEASES OF THE LARYNX AND TRACHEA.

	PAGE
Affections of the Larynx and Trachea.—Points relating to the Anatomy and Physiology of the Larynx which are Involved in the Consideration of Diseases in this Situation.—Acute Simple Laryngitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Subacute Laryngitis.—Chronic Laryngitis.—Laryngitis Hypoglottica.—Laryngitis with Fibrinous Exudation: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Œdema of the Glottis.—Spasm of the Glottis.—Nervous Cough.—Nervous Aphonia.—Paralysis of the Laryngeal Muscles.—Morbid Growths within the Larynx	197

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

PERICARDITIS.

Introductory Remarks.—Acute Pericarditis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Chronic Pericarditis.—Pneumo-Pericarditis	225
--	-----

CHAPTER II.

ENDOCARDITIS.—MYOCARDITIS.—DISEASES OF THE CORONARY ARTERIES.

Simple Endocarditis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Acute Ulcerative Endocarditis.—Myocarditis	237
--	-----

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment	248
---	-----

CHAPTER IV.

Hypertrophy and Dilatation of the Heart.—Atrophy of the Heart.—Obesity and Fatty Degeneration of the Heart.—Parenchymatous Degeneration of the Heart.—New Growths and Parasites in the Heart.—Rupture of the Heart.—Thrombosis of the Heart.—Embolism of the Pulmonary Artery	265
---	-----

CHAPTER V.

Functional Disorder of the Heart.—Exophthalmic Goitre.—Angina Pectoris.—Thoracic Aneurism	275
---	-----

SECTION THIRD.

DISEASES AFFECTING THE HÆMATOPOIETIC SYSTEM.

CHAPTER I.

DISEASES OF THE HÆMATOPOIETIC SYSTEM.

Introductory Remarks.—Simple or Benign Anæmia.—Chlorosis	291
--	-----

CHAPTER II.		PAGE
Leucocythæmia		298
CHAPTER III.		
Pseudo-Leucocythæmia.—Hodgkin's Disease		307
CHAPTER IV.		
Pernicious Anæmia		311
CHAPTER V.		
Addison's Disease		317

SECTION FOURTH.

DISEASES AFFECTING THE DIGESTIVE OR CHYLOPOIETIC SYSTEM.

CHAPTER I.	
DISEASES OF THE TONSILS, THE PHARYNX, THE ŒSOPHAGUS, AND THE PAROTID GLANDS.	
Introductory Remarks.—Tonsillitis.—Pharyngitis.—Diseases of the Œsophagus.— Parotiditis.—Mumps	324
CHAPTER II.	
INFLAMMATORY DISEASES OF THE STOMACH AND OF THE DUODENUM.	
Acute Gastritis.—Subacute Gastritis.—Chronic Gastritis.—Phlegmonous Gastritis.— Chronic Interstitial Gastritis.—Gastro-Duodenitis.—Duodenitis	334
CHAPTER III.	
STRUCTURAL DISEASES OF THE STOMACH.	
Softening.—Gastric Ulcer.—Carcinoma of the Stomach.—Dilatation of the Stomach. —Degeneration of the Gastric Tubes.—Waxy Degeneration of the Stomach . . .	350
CHAPTER IV.	
FUNCTIONAL DISORDERS, OR NEUROSES OF THE STOMACH.	
Introductory Remarks.—Motor Neuroses (Nervous Vomiting; Peristaltic Unrest; Nervous Eructation; Rumination; Incontinence of the Pylorus; Atony).—Sen- sory Neuroses (Gastralgia; Polyphagia, Malacia and Pica, Polydipsia, and Dipso- mania).—Secretory Neuroses (Hyperacidity and Hypersecretion).—Nervous Dys- pepsia.—Gastrorrhagia.—Inanition	373
CHAPTER V.	
INFLAMMATORY DISEASES OF THE INTESTINE.	
Anatomical Characters of Acute Dysentery.—Sporadic Dysentery.—Epidemic Dysen- tery.—Chronic Dysentery.—Inflammation and Perforation of the Cæcum.—Fecal Abscess.—Inflammation and Perforation of the Vermiform Appendix.—Colitis.— Proctitis.—Acute Enteritis.—Subacute and Chronic Enteritis	397

CHAPTER VI.

STRUCTURAL DISEASES OF THE INTESTINE.

	PAGE
Intestinal Ulcers.—Duodenal Ulcer.—Embolism of the Superior Mesenteric Artery.—Carcinoma of the Intestine.—Waxy Degeneration of the Intestine.—Structural Lesions causing Intestinal Obstruction.—Intussusception.—Strangulated Hernia within the Abdomen.—Rotation or Twisting of Intestine.—Compression and Stricture of the Intestine.—Obstruction from Impaction of Feces, Gall-Stones, Enteroliths, and Foreign Bodies.—Functional Obstruction	427

CHAPTER VII.

FUNCTIONAL DISEASES OF THE INTESTINE.

Diarrhœa.—Enterorrhagia.—Constipation.—Intestinal Colic.—Enteralgia.—Lead Colic.—Colic from Copper.—Passage of Gall-Stones	445
--	-----

CHAPTER VIII.

SPORADIC CHOLERA.—CHOLERA INFANTUM.—ASIATIC CHOLERA.

Sporadic Cholera: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Cholera Infantum.—Epidemic Cholera: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Prevention; Treatment	471
---	-----

CHAPTER IX.

INTESTINAL WORMS.

<i>Ascaris lumbricoides</i> .— <i>Oxyuris vermicularis</i> .— <i>Trichocephalus dispar</i> .— <i>Ascaris mystax</i> .— <i>Tæniæ</i> .— <i>Trichina spiralis</i> .— <i>Anchylostoma duodenale</i>	498
--	-----

CHAPTER X.

DISEASES OF THE PERITONEUM.

Acute Diffuse Peritonitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Circumscribed Peritonitis.—Chronic Peritonitis.—Hydro-peritoneum	511
--	-----

CHAPTER XI.

DISEASES OF THE LIVER.

Suppurative Hepatitis.—Chronic Interstitial Hepatitis (Cirrhosis).—Hypertrophic Cirrhosis of the Liver.—Syphilitic Hepatitis.—Acute Yellow Atrophy of the Liver.	532
--	-----

CHAPTER XII.

DISEASES OF THE LIVER (CONTINUED).

Fatty Liver.—Parenchymatous Degeneration of the Liver.—Waxy Liver.—Cancer of the Liver.—Other New Growths in the Liver.—Hydatid Tumors of the Liver.—Multilocular Echinococcus.—Other Parasites in the Liver.—Pigmentary Deposits in the Liver.—Hypertrophy and Atrophy of the Liver.—Changes in the Position and in the Shape of the Liver.—Congestion of the Liver.—Portal Thrombosis.—Adhesive and Suppurative Pylephlebitis	550
---	-----

CHAPTER XIII.

DISEASES OF THE BILIARY PASSAGES.—JAUNDICE.

	PAGE
Inflammation of the Biliary Passages.—Dilatation of the Gall-bladder; Cancer of the Gall-bladder.—Jaundice, or Icterus.—Weil's Disease.—Acute Febrile Icterus.—Infectious Icterus.—Functional Affections of the Liver	567

CHAPTER XIV.

Diseases of the Spleen.—Diseases of the Pancreas	578
--	-----

SECTION FIFTH.

DISEASES AFFECTING THE NERVOUS SYSTEM.

CHAPTER I.

DISEASES RELATING TO THE CEREBRAL AND THE SPINAL CIRCULATION.

Cerebral Hyperæmia.—Cerebral Anæmia.—Cerebral Embolism and Thrombosis.—Thrombosis of the Cerebral Sinuses.—Capillary Embolism and Thrombosis of the Brain.—Cerebral Hemorrhage.—Topical Diagnosis of Cerebral Diseases.—Meningeal Hemorrhage.—Insolation, or Sunstroke.—Hyperæmia and Anæmia of the Spinal Cord and its Meninges.—Spinal Hemorrhage	585
---	-----

CHAPTER II.

INFLAMMATORY DISEASES OF THE MENINGES OF THE BRAIN AND OF THE SPINAL CORD.—HYDROCEPHALUS.—HYDRORRHACHIS.

Pachymeningitis and Hæmatoma of the Dura Mater.—Simple Acute Cerebral Meningitis: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Chronic Cerebral Meningitis.—Tuberculous Meningitis.—Acute Spinal Meningitis.—Chronic Spinal Meningitis.—Cervical Hypertrophic Meningitis.—Cerebro-spinal Meningitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Hydrocephalus.—Hydrorrhachis.—Syringomyelia	631
---	-----

CHAPTER III.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE BRAIN.

Encephalitis.—Abscess of the Brain.—Inflammatory Softening of the Brain.—Diffuse Sclerosis of the Brain.—Cerebral Paralysis of Children.—Infantile Spastic Hemiplegia.—Chronic Bulbar Paralysis.—Acute Bulbar Paralysis.—Intracranial Tumors.—Cerebral Syphilis	657
---	-----

CHAPTER IV.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE SPINAL CORD.

General Considerations relating to Inflammatory and Structural Diseases of the Spinal Cord.—Myelitis, Acute and Chronic.—Cerebro-spinal Sclerosis.—Locomotor Ataxia, or Posterior Spinal Sclerosis.—Hereditary Ataxia.—Acute Anterior Poliomyelitis.—Acute Anterior Poliomyelitis in the Adult.—Subacute and Chronic Anterior Poliomyelitis.—Progressive Muscular Atrophy.—Spastic Spinal Paralysis.—Amyotrophic Lateral Sclerosis.—Compression of the Spinal Cord.—Intra-spinal Tumors.—Pseudo-hypertrophic (or Myosclerotic) Paralysis	670

PRACTICE OF MEDICINE,
OR
SPECIAL PATHOLOGY.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

Of the Different Aspects under which Individual Diseases are to be Considered in Treating of the Practice of Medicine, or Special Pathology ; namely, Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention, and Treatment—Sense of the term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the terms Acute, Sub-acute, and Chronic—Symptoms or Events incidental to Diseases sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology—Nosological Arrangement adopted in this Work.

THE *Practice of Medicine, or Special Pathology*, treats of individual diseases. In this department of medical study individual diseases are considered under several different aspects. One of these aspects relates to the appreciable changes found after death. These changes belong to morbid anatomy. Some diseases are characterized by morbid appearances in the parts affected, and other diseases are not accompanied by any lesions which are appreciable. The latter are distinguished as *functional diseases*. The term *anatomical characters* of a disease expresses the changes belonging to morbid anatomy which occur in connection with that disease. This term will be adopted as the title, usually, of the first aspect under which diseases not functional will be considered.

Another aspect relates to the phenomena or events which compose the *clinical history* of a disease. Under this head will be embraced precursory or prodromic events, the symptoms which accompany the access and those which occur during the career of the disease under consideration, the order of their succession, the laws regulating the development and progress of the disease, etc. This will constitute the second of the different aspects under which individual diseases, severally, are to be considered.

A third aspect relates to the *pathological character* of a disease. This aspect embraces what is known of the nature and seat of the morbid conditions which constitute or enter into the disease under consideration.

A fourth aspect relates to *etiology*, or the *causation* of a disease. Under this head will be stated what is known of the cause or causes of each individual disease.

A fifth aspect relates to *diagnosis*, or the discrimination of diseases. The application of the methods of investigation which by means of symptoms, laws, etc. enables the physician to recognize the disease under consideration, and to distinguish it from other diseases, will be considered under this head, Physical signs, whenever these are available in the diagnosis of a disease, will be embraced under this head.

A sixth aspect relates to *prognosis*. This aspect embraces the intrinsic tendencies of diseases as regards termination in death or recovery. The circumstances which denote, on the one hand, a favorable, and, on the other hand, an unfavorable, progress of diseases will come under the head of the prognosis. And the consequences more or less remote, or sequels, may sometimes be conveniently embraced under this head.

A seventh aspect relates to the *treatment* and *prevention* of a disease. The consideration of the treatment of each disease will embrace the indications for therapeutic measures and the remedies which experience has shown to be useful in that disease. Hygienic measures will also enter into the consideration of treatment. Prophylactic measures of treatment will claim consideration in treating of different diseases, and the measures which remove or obviate the causes of disease will often be found to be not less important than the judicious application of principles of therapeutics.

Before entering upon individual diseases it may be well to inquire what is meant by this use of the term *individual*, and whence does a disease derive its individuality. An individual disease differs from other diseases sufficiently for it to be regarded as separate and distinct. The sense of the term individual in this application is analogous to that of species in natural history. The individuality of a disease is established by distinctive features pertaining to its clinical history. These distinctive features may be derived exclusively from the seat of the disease. Thus, pleuritis and pericarditis are inflammatory diseases of a serous membrane, and have essentially the same pathological character; but the different anatomical relations of the pleura and of the pericardium furnish sufficient points of distinction to constitute each of these affections an individual disease. In other instances distinctive features are derived from the processes belonging to disease. Inflammatory diseases, for example, differ essentially from those which are not inflammatory. Again, certain diseases derive each an essential distinction from its exclusive dependence on a special cause. It is sufficient to show that a disease is produced by a special cause to establish its claim to be regarded as an individual disease.

An individual disease is to be distinguished from individual cases of disease. An individual case of disease has a relation to an individual disease like that of a particular man to the human species. The study of individual cases of disease belongs to clinical medicine. Some individual diseases embrace several varieties. Empyema and pneumo-hydrothorax may be considered as varieties of pleuritis, both consisting in inflammation of the pleura, the former differing from ordinary pleuritis in the fact that the liquid contained in the cavity of the pleura is purulent, and the latter differing in the fact that air and liquid are contained in that cavity. The several types of intermittent fever distinguished as tertian, quotidian, etc. are different varieties of one disease. In the progress of medicine certain diseases have come to be considered as essentially distinct which were formerly regarded as different varieties of one disease. This is true of all the eruptive fevers. It is probable that certain diseases now considered as individual will be hereafter found to be divisible into two or more.

Differences as regards severity and duration constitute a basis of the division of a disease into varieties. The same disease may be either *acute*, *subacute*, or *chronic*. A disease is acute when it has a certain degree of intensity and runs a rapid career. In general, an acute disease is of sufficient gravity to confine the patient to the bed. The subacute variety of a disease has less intensity, frequently not compelling the patient to keep the bed, and perhaps not preventing him from being about or even pursuing his usual occupation. The chronic variety exists when a disease is subacute and has continued for

a considerable period. Some diseases are never chronic. This term, for instance, is not applicable to typhus or typhoid fever. The division into varieties, based upon the differences just named, is especially applicable to inflammatory diseases.

The list of individual diseases embraces some, recognized as such for the sake of convenience, which in reality are only effects or symptoms of diseases. Jaundice, for example, is an effect or symptom occurring in connection with different diseases. Dropsy is in the same category. It is, however, convenient to consider jaundice and the different forms of dropsy as if they were individual diseases. In fact, if we were better acquainted with the primary or elementary forms of disease, it would probably appear that not a few of the diseases now considered as individual are only manifestations of morbid conditions at present occult, the latter constituting the true diseases.

A point of distinction among diseases, interesting and of much practical importance, relates to duration. Some diseases continue for a definite period, never exceeding certain limits in this regard. The duration of certain diseases is regulated by fixed laws; that is, they rarely end until after the lapse of a certain number of days, and never exceed a certain number of days in their continuance. The continued and eruptive fevers are examples of diseases the duration of which has definite limits. Intermittent fever, on the other hand, has no fixed or definite duration if its course be not interfered with. Diseases which tend intrinsically to end after a certain time are distinguished as *self-limited*. The laws of different diseases with respect to self-limitation are often to be taken into account in the employment of therapeutical measures; and it is obvious that these laws are to be considered in estimating the amount of curative influence exerted by methods of treatment. One of the most striking and important of the characteristics of modern medicine is the knowledge which has been acquired of the self-limitation of different diseases. Facts have shown that even pulmonary phthisis in some cases ends in recovery from an intrinsic tendency thereto.

In treating of individual diseases some classification of them is essential. The classification of diseases constitutes a division of medicine called *nosology*. The history of medicine furnishes many nosological systems, the relative merits of which it would be useless to discuss. Undoubtedly, a scientific mode of classifying diseases would be to arrange them after essential points of distinction relating to their pathological character; but with our present knowledge of the pathological character of different diseases to do this is impracticable. A nosological arrangement on this basis must be deferred for a future period, when pathology shall have advanced far beyond its present condition. The same remark is applicable to any arrangement based on differences as regards the causes of diseases. Our present knowledge of etiology is not sufficient to furnish the basis of a permanent nosology. Inasmuch as the chief object of a classification is convenience, the proper course to be pursued, evidently, is to adopt a provisional plan which will best subserve this object; and the most convenient classification at the present time is that which has of late years been adopted by the majority of authors and teachers. This consists in dividing diseases into first, *general*; and second, *local*. General diseases are those which involve more or less disturbance of the whole system, this disturbance not having been preceded by any known local affection, local affections, if they occur, being developed secondarily. To this class belong the essential fevers. Under the head of constitutional diseases it is convenient to include some in which the local manifestations have no fixed seat and sometimes differ in character. Rheumatism and gout are constitutional diseases, the chief manifestations consisting of local affections differently situated in different cases and at different periods in the same case. The local affection,

however, is in each essentially the same wherever seated. Syphilis is another constitutional disease manifesting itself in local affections which differ not only in situation, but in character. The want of fixedness or uniformity in the seat of local affections proceeding from constitutional disease, and their diversity in character in some instances, are the grounds for placing certain diseases in this class. A large proportion of the affections nosologically considered as local probably proceed from constitutional disease; but as the local affections are fixed and uniform, and our knowledge of the constitutional disease is, for the most part, inferential, it is more convenient to arrange them in the second division.

The second division, or local diseases, will embrace all which are not reckoned as general or constitutional. The number of local diseases is far greater than that of the diseases embraced in the first division. It is necessary to arrange them into subdivisions. The most convenient plan is to distribute them into groups corresponding to the distribution of the different organs of the body into physiological systems. According to this plan the different local diseases are subdivided as follows:

1. Diseases affecting the respiratory system;
2. Diseases affecting the circulatory system;
3. Diseases affecting the hæmatopoietic system;
4. Diseases affecting the digestive or chylipoietic system;
5. Diseases affecting the nervous system;
6. Diseases affecting the genito-urinary system.

The foregoing arrangement of local diseases will be adopted, and they will be considered in sections corresponding to the groups just enumerated. Afterward a section will be devoted to general diseases.

[An eighth section has been added by the editor to include the *zoonoses*, or diseases transmitted from animals to man. The chief of these are trichiniasis, rabies, actinomycosis, anthrax, and glanders. It seems most appropriate, however, to classify the first mentioned among the intestinal parasites, as was done by the author.—H.]

Of the diseases belonging to these several groups, those only will be considered which are medical as distinguished from surgical. The surgical diseases are those which are either external or in accessible situations. Thus, diseases of the mouth, throat, and nasal passages, of the anus and rectum, of the urethra and bladder, of the eye and ear, and of the vagina and uterus, fall within the province of surgery. Diseases of the skin, being external, belong to surgery, notwithstanding that they receive special attention from the physician perhaps oftener than from the surgeon. As an additional reason for not including them among the diseases to be considered in this work, there are many treatises devoted specially to their consideration.

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

ACUTE PLEURITIS.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory.—Acute Pleuritis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis.

OF the diseases affecting the respiratory system, an obvious division is based on the existence or non-existence of inflammation. Inflammatory diseases are seated respectively in three important structures comprised in the organs of the respiratory apparatus—namely, the mucous membrane lining the air-passages, the serous membranes which invest the lungs, and the pulmonary parenchyma. Inflammation affecting the structures just named gives rise to pleuritis¹ or pleurisy, pneumonitis or pneumonia, and bronchitis. These will be treated of in the order in which they have just been enumerated. The first disease to be considered—namely, pleuritis—may exist as an acute and as a subacute or chronic affection, the inflammation being diffused over the affected membrane. These two varieties of the disease will claim separate consideration. Other varieties, to be considered separately, are empyema, pneumo-hydrothorax, and circumscribed pleuritis. It will be convenient to notice, in connection with these varieties of pleuritis, the dropsical affection known as hydrothorax.

Acute Pleuritis.

The pleura, like other serous membranes, is divided into a visceral and a parietal layer. The free surfaces of these two layers are smooth, polished, and covered with a single layer of flat nucleated cells called epithelial cells or endothelial cells.² These cells rest upon fibrillated connective tissue containing a network of elastic fibres, blood-vessels, and lymphatic vessels. The pleural cavities contain normally a small quantity of serum.

ANATOMICAL CHARACTERS.—The first noticeable change in acute pleuritis is redness of the pleura from active hyperæmia of the vessels within and beneath the affected portion of the pleural membrane. Small extravasations of blood, or ecchymoses, are not infrequently present at an early stage of the

¹ With a view to uniformity as regards nomenclature, the terms pleuritis and pneumonitis are used instead of pleurisy and pneumonia.

² It has until recently been held that the peritoneal, pericardial, and pleural cavities are large lymph-spaces lined by a variety of connective-tissue cells called endothelium. Recent investigations have cast doubt upon this view, and have made it probable that these serous cavities are derived from the endoblast, and that their lining cells are epithelial in origin.

inflammation. The pleura loses its glistening appearance, and becomes dull and opaque in consequence of desquamation of the epithelium and beginning exudation.

Very soon the surface of the pleura becomes covered either in patches or continuously with a delicate layer of fibrin. The fibrin appears first in the form of little clumps, which increase in thickness and coalesce with each other. The opposing surfaces of the pleura are agglutinated by the fibrin. The fibrinous exudation was called by the older writers coagulable lymph and false membrane. The fibrin varies in its microscopical appearance, being sometimes granular, sometimes homogeneous, and sometimes finely fibrillated. Certain constituents of the fibrin are furnished by the exuded liquor sanguinis, others by the altered tissue-elements and leucocytes. In some cases of pleuritis, particularly of the circumscribed variety, fibrin containing a few pus-cells is the sole inflammatory product. This form of the affection is called *fibrinous* or *dry pleuritis* (*pleuritis sicca*).

More commonly, acute pleuritis is of the *sero-fibrinous* variety. In this variety, in addition to the fibrinous coating of the pleura, the cavity contains serum, varying in quantity from a few ounces to several pints. The serum may be clear, but it is usually turbid from admixture with pus-cells and flocculi of fibrin. Upon microscopical examination both pus-cells and red blood-corpuscles are found in the fluid. The red blood-corpuscles may be so abundant as to stain the fluid red. The pleuritis is then called *hemorrhagic*, a variety observed especially in certain dyscrasiæ, such as scorbutus, and in tuberculous and cancerous disease of the pleura.

If the inflamed pleura be examined microscopically, a considerable number of emigrated white blood-corpuscles are found both in the pleural tissue and in the fibrinous layers on its surface. Part of the epithelial cells which normally cover the pleura undergo necrosis and desquamate, and a part, less severely affected by the inflammatory irritant, proliferate and produce flat cells of various shapes with vesicular nuclei. Some of the connective-tissue cells in the pleura swell up and also proliferate. The lymphatics of the pleura are dilated, and frequently contain fibrin, pus-cells, or proliferated endothelium. In from four to six days after the onset of the inflammation new-formed capillaries, which are offshoots from the pleural capillaries, make their appearance in the deeper parts of the layer of fibrin and cells covering the pleura. If at the height of the inflammatory process a microscopical section through the false membrane and the subjacent pleura be examined, the following layers can be distinguished: superficially, a layer of fibrin containing pus-cells; beneath this, a layer of embryonic or granulation-tissue composed of blood-vessels, leucocytes, and variously shaped larger cells which are derived from the epithelial cells and the connective-tissue cells of the pleura, and are intended for the formation of new connective tissue; and thirdly, the pleural membrane itself, containing dilated blood-vessels, leucocytes, and proliferating connective-tissue cells. In the layer of granulation-tissue more or less fibrin is also present. Some pathologists regard the proliferative changes in the epithelial and connective-tissue cells as purely regenerative, and separate them from the strictly inflammatory processes in the blood-vessels which give rise to the exudation of serum, fibrin, and pus.

The terminations of acute pleuritis are either in death, in resolution, in chronic pleuritis, or in empyema.

If resolution take place, the serum is absorbed, the fibrin, pus-cells, and red blood-corpuscles disintegrate and are likewise absorbed, and the granulation-tissue is changed into fibrillated connective tissue. In this formation of connective tissue, fibrillated basement-substance appears between the cells, which are gradually changed into flat, fusiform, or branching connective-tissue cells.

Some of the cells and some of the blood-vessels disappear. The remaining blood-vessels, which at first have thin, easily-ruptured walls, acquire more compact coats. The new connective tissue develops both in the form of diffuse fibrous thickening of the pleura, and in the form of thread-like or band-like adhesions between the two pleural surfaces. The long adhesions are produced by villous outgrowths of the granulation-tissue into the fibrin and fluid which during the inflammation separate the pleural surfaces from each other. It is probable that they may also be caused by stretching of short adhesions by the movements of the pleura. It will be noted that after the most favorable termination of pleuritis the pleura does not return to its normal state, but is left with a new growth of connective tissue, which binds the pleural surfaces together over a great or less extent. In this way the pleural cavity may become entirely obliterated by adhesions. The adhesions are at first weak, and may be broken by active exercise or by acts of coughing. Hemorrhage into the pleural cavity may in this way occur.

If after the lapse of three or four weeks the inflammatory products continue to increase, or remain stationary, or diminish very slowly, the disease has passed into the chronic stage.

When pus-cells accumulate in sufficient number, the exudation becomes purulent and the disease is called empyema. Chronic pleuritis and empyema will be considered subsequently.

The effects of large accumulations of fluid in the pleural cavity upon the lungs are of importance. If the lung be not restrained by adhesions, it is pressed upward and inward against the vertebral column. If the fluid accumulation be very extensive, the compressed lung loses all the physical characters dependent upon the presence of air in the air-cells. It resembles a mass of flesh, and is therefore said to be *caruified*. The pulmonary structure, however, remains intact, and it is capable of being inflated after death nearly or quite to the same extent as if it had not undergone this compression. A similar expansion may take place during life after the absorption of the fluid. So large an accumulation of liquid, however, occurs much oftener in chronic than in acute pleuritis.

Pleuritis may be general or circumscribed. Primary or idiopathic pleuritis is general. Circumscribed pleuritis—which, as already remarked, is often dry—is usually secondary to some affection of parts adjacent to the pleura. Circumscribed pleuritis may affect the pulmonary, the costal, the diaphragmatic, or the mediastinal pleura. Even in circumscribed pleuritis the two opposing surfaces of the pleura are usually inflamed—a circumstance which goes to show that the inflammatory irritant is contained in the exudation, for the opposed surfaces of the pleura have different vascular supplies.

CLINICAL HISTORY.—The most convenient division of acute pleuritis into stages is to consider as the *first stage* the period from the attack to the time when an appreciable quantity of liquid effusion has taken place; the *second stage* will extend to the time when the liquid begins sensibly to diminish; and the *third stage* will comprise the period occupied in the absorption of the liquid. The first stage, or the period anterior to an appreciable amount of liquid effusion, is usually of short duration. The physical signs may show the presence of liquid within a few hours from the date of the attack. This stage rarely extends beyond twenty-four hours. The second stage is of variable duration. The accumulation of liquid may go on with more or less rapidity. When the maximum amount is reached, the quantity may remain stationary for some time or absorption may speedily begin. The liquid may diminish under the effect of treatment, and renewed effusion take place. The disease does not, of course, advance beyond the second stage in the cases in which it

eventuates in chronic pleuritis. If a considerable quantity of liquid remain at the end of from three to four weeks, the disease is to be considered as having become chronic. In cases which pursue a favorable course considerable progress should be made in the removal of the liquid after this lapse of time. The duration of the third stage, or the stage of absorption, is quite variable. Generally, some liquid remains when the general symptoms denote convalescence, and even after the patient has apparently recovered. The physical signs may show the presence of fibrin for some time after the date of convalescence. From what has been stated it follows that the duration of the career of the disease is from two to four weeks.

The *invasion* is often sudden and without premonition. In a certain proportion of cases, however, pain or soreness is felt for one, two, or three days before the development of acute inflammation. The development of acute inflammation is characterized by symptoms which sufficiently mark the date of its occurrence. It is sometimes ushered in by a well-pronounced chill, accompanied perhaps with rigors. Chill and rigors, however, are by no means so frequent, or, as a rule, so marked, as in cases of pneumonitis. Not infrequently chilly sensations and slight shiverings only are experienced.

Pain in the affected side attends the onset of acute inflammation in a large majority of cases. The pain is usually intense. It is sharp, cutting, or lancinating in character. It is felt especially in the act of inspiration; and it increases during inspiration, often becoming so severe that the act is instinctively arrested before being completed. Coughing and sneezing occasion severe pain. The movements of the body are painful, but in a far less degree than the respiratory movements. The pain is referred to the middle and lower third of the affected side of the chest, and is often diffused over the anterior, the lateral, and sometimes the posterior portion. It is not, as a rule, circumscribed or limited to a small space. The morbid sensitiveness of the inflamed pleura seems to me adequate to account for the production of acute pain as a result of the movements of the pleural surfaces upon each other and the stretching of the membrane, without requiring the hypothesis that either intercostal neuralgia or an affection of the costal muscles is superadded to the inflammation. Pain, with the characters just described, is almost uniformly present in acute pleuritis, but cases occur in which it is not marked, and is even wanting, other symptoms showing the inflammation to be acute.

Pyrexia is coincident with the development of the inflammation. The pulse is increased in frequency, rarely, however, exceeding 100 per minute. The temperature of the surface is raised. The thermometer in the axilla shows more or less intensity of fever, but the rise rarely exceeds 102°. As a rule, there is less pyrexia than in cases of pneumonitis. The usual concomitants of symptomatic fever—namely, thirst, anorexia, pain in the head and loins, restlessness, muscular weakness, etc.—are more or less marked. The intensity of the fever and of the general or constitutional disturbance varies much in different cases of this as of other inflammations. In rare instances the fever is intense, the temperature rising to 105° or higher, with a corresponding intensity of other constitutional symptoms (pleuritis acutissima). In most of these instances the pleuritis is of the suppurative variety, or empyema.

A comparison of the two sides of the chest as regards temperature shows a slightly higher temperature on the affected side, the difference being a fraction more than one degree.

Cough is usually present, but it is sometimes wanting. The pain in coughing leads instinctively to efforts to repress it, and this gives to the mode of coughing a character denoted by the term suppressed. The patient succeeds,

to a certain extent, in these efforts. The expectoration is slight or wanting, and when present it consists of simple mucus. The exceptions to this rule are the cases in which the development of pleuritis is preceded by bronchitis. When these affections are associated it is merely a coincidence; there is no tendency in either one to give rise to the other.

The respirations are increased in frequency, but not greatly. Their increased frequency at this period is due to an arrest of the inspiration before it is completed, in consequence of pain. The patient instinctively multiplies the respiratory acts to compensate for the want of a full inspiration. As a rule, the patient in lying chooses a position on the healthy side, the weight of the body upon the affected side increasing the pain and soreness. This rule is by no means without exceptions. Not infrequently the decubitus is either dorsal or diagonal.

These symptoms constitute the clinical history of this disease during the first stage, or prior to effusion. They continue into the *second stage*, but after a certain amount of effusion has taken place they are materially modified. The pain is notably lessened, and may disappear except on forced breathing. The acts of coughing are less painful and the efforts at suppression are less apparent. The pyrexia diminishes, and may even cease during this stage. Other evidences of constitutional disturbance are less marked. The patient seems better, and may be able to sit up and perhaps walk about the room. The respirations are more or less frequent. Their frequency now depends on the compression of the lung by liquid. Their frequency will be great, other things being equal, in proportion to the quantity of liquid and the rapidity of the effusion. If a considerable amount of liquid be rapidly effused, the respirations are rapid; the patient suffers from a painful sense of the want of breath, or dyspnœa, and may be obliged to maintain the sitting posture. If the quantity be not large, and the effusion have not taken place rapidly, the patient will not be likely to suffer from dyspnœa while remaining quiet, but exercise will cause panting and a sense of the want of breath. Even with the pleural sac distended with liquid, the only effect on the breathing may be an increase of the frequency of the acts to twenty-five or thirty per minute, without suffering so long as the patient remains quiet. The diminution or cessation of pain is due to the restrained movements of the pleural surfaces upon each other in consequence of the presence of the liquid and fibrin, the latter perhaps agglutinating the portions of those surfaces which are in contact. The change as regards fever and other constitutional symptoms proceeds, in part, from the removal of the conditions causing pain, and partly because, after exudation has taken place, the disease is mitigated from an intrinsic tendency to decrease. The patient now, as a rule, prefers to lie upon the affected rather than the healthy side, as in this position he is able to expand more freely the opposite lung. To this rule, however, there are exceptions, and the decubitus in this stage, as in the first stage, is frequently either dorsal or diagonal.

During the stage of *absorption* pain is either wanting or is produced only by muscular efforts; fever has disappeared; cough diminishes or ceases; the respirations become less and less frequent, and are less hurried by exercise; the appetite and digestion return, and the normal condition of all the functions is gradually restored. During this stage the patient is convalescent; he is able to be out of doors, and perhaps to resume in part his usual avocation and habits. Convalescence is declared, and the symptoms, both general and local, may appear to denote that recovery has taken place while some liquid effusion still remains; the fibrin is not fully absorbed, and the formation of new tissues leading to permanent adhesions is going on. A sense of weakness in the affected side, together with some soreness or pain on unusual

exertion, frequently continues for some time after the termination of the career of the disease.

Strümpell states that in the first stage of the disease, while effusion is taking place, the secretion of urine is notably diminished, and that the beginning of the absorption of the effused liquid is shown by a notable increase in the quantity of urine. This increase may thus serve to indicate that the disease has advanced to the second stage.¹

In primary or idiopathic pleuritis the inflammation, as already stated, is diffused over the pleural membrane; it is general, not circumscribed. If circumscribed, it is a complication of some other pulmonary affection, as a rule. It will be seen hereafter that it occurs as a complication of pneumonitis and pericarditis, but it is generally, under these circumstances, subacute. Primary pleuritis does not lead to pneumonitis, except that the air-cells in immediate proximity to the pleura are sometimes involved; nor does it involve any tendency to bronchitis. It is a unilateral disease—that is, it affects the pleura of one side only. The exceptions to this rule are so infrequent that the disease, when bilateral or double, may be presumed to be secondary to another pulmonary affection, generally tuberculosis.

PATHOLOGICAL CHARACTER.—This disease is an example of acute inflammation affecting a serous membrane, and may be regarded as a type of all acute inflammations of serous membrane. Pleuritis and inflammations of other serous membranes are characterized by fibrinous exudation as a constant event. This event, the accumulation of liquid in the closed cavity, and the development of connective tissue are characteristics of these inflammations.

CAUSATION.—Acute pleuritis may be either *primary* or *secondary*. The disease is primary when it occurs independently of any other affection. Primary or idiopathic pleuritis is attributed in certain cases to the action of cold. This has so long been considered as a frequent source of a great number of diseases that patients at once are led to refer an attack to some exposure, often, doubtless, when it had no causative agency or at most acted only as an exciting cause. Still, it is probable that the disease sometimes originates in this way. Acute pleuritis may be produced traumatically by contusions, especially if accompanied with fracture of the ribs, and by penetrating wounds. It is remarkable, however, that severe injuries of the chest often occur without giving rise to general pleuritis.

Primary pleuritis is much less frequent than was formerly supposed. In the majority of cases of pleuritis careful examination, both before and after death, shows the pleuritis to be secondary to some local or constitutional disease. Affections of parts adjacent to the pleura play an important rôle in the causation of pleuritis. The most important of these local affections which cause secondary pleuritis are lobar pneumonitis, lobular pneumonitis, pulmonary tuberculosis, infarctions, abscesses and gangrene of the lung, cancer and perforations of the œsophagus, caseous tubercles in the bronchial glands, caries of the vertebræ and ribs, and inflammations in the mediastinum. The various inflammations of the peritoneum and of the pericardium often lead to pleuritis.

Pleuritis is a frequent complication of many infectious diseases, such as scarlatina, variola, pyæmia, septicæmia, and acute articular rheumatism. It occurs also not infrequently in Bright's disease, scorbutus, and gout.

Pleuritis may be secondary to other diseases of the pleura, such as cancer, sarcoma, and tubercle.

¹ *Lehrbuch der Speciellen Pathologie und Therapie der inneren Krankheiten*, Leipsic, 1885.

In cases which appear to be primary pleuritis, careful search should be made for some hidden cause, such as tuberculosis or Bright's disease. In some cases, however, no cause can be discovered.

[Most pathologists of the present day regard pleurisy as an infectious disease, this opinion being based upon the frequency with which micro-organisms such as the streptococcus pyogenes, the pneumococcus of Fraenkel, and the bacillus tuberculosis are found in the inflammatory products. It must, however, be admitted that if the disease is infectious, its causes are multiple—a view which is confirmed by the diversity of its pathological products and the variety of its clinical course. The commonest cause of pleurisy is tuberculosis. The tubercular origin of many cases of pleurisy which were at first regarded as benign has become manifest in the lapse of time by the development of pulmonary phthisis.

The intimate pathological relationship between pleurisy and articular rheumatism is an observation of comparatively recent date. Probably most of the cases of acute pleurisy which run a favorable course are of rheumatic nature.—H.]

DIAGNOSIS.—Although the symptoms which enter into the clinical history of acute pleuritis are sufficiently characteristic to point to the existence of the disease, they are not sufficient for the diagnosis in all cases. The characteristic pain is not peculiar to the disease. The pain in some cases of intercostal neuralgia and pleurodynia is as strongly marked as in acute pleuritis, and these three affections were formerly often confounded in practice. Moreover, the pleuritic pain in some cases of pneumonitis is as intense as when the pleuritis is a primary disease, and the former disease has not infrequently been mistaken for the latter. On the other hand, acute pleuritis is liable to be overlooked in the cases in which pain is slight or wanting. More or less fever is present in acute pleuritis, but this symptom may be associated accidentally with intercostal neuralgia; it is likely to be present in pleurodynia, and it exists, of course, in pneumonitis. The diagnosis is to be based on the physical signs taken in connection with the symptoms. The latter are of importance, and, indeed, are essential in determining whether the affection be acute or not. The differential diagnosis consists in discriminating between the disease under consideration and intercostal neuralgia, pleurodynia, and pneumonitis.

The diagnosis in the first stage, with the aid of physical signs, cannot always be made with positiveness. Examination of the chest by inspection will show restrained movements on the side to which the pain is referred, the movements on the opposite side being increased, while on percussion distinct disparity between the two sides may not be found; and on auscultation the murmur of respiration is more or less weakened on the affected side. These signs are due to the fact that the pain leads instinctively to a diminished use of the lung on the side affected, while the use of the other lung is increased. They are equally present when the pain is incident to the affections from which this disease is to be discriminated. A slight friction murmur may be discovered in this stage; and if present its diagnostic significance is important. It shows that pleuritis exists, and the discrimination then lies between pleuritis as a primary disease or as a complication of pneumonitis. To decide this point at once is not always easy. The diagnostic sign of pneumonitis—namely, the crepitant r  le, if present—settles the question; but as this sign is by no means present uniformly in pneumonitis, its absence does not authorize the exclusion of that disease. The same remark is applicable to the characteristic expectoration of pneumonitis. It must be confessed that in a certain number of cases this differential diagnosis requires some delay. A

friction murmur is heard in only a certain proportion of cases during the first stage, and if absent the signs belonging to the second stage are essential in order to render the diagnosis positive.

The signs belonging to the second stage are usually present without much delay. If the disease be idiopathic pleuritis, after the lapse of twelve or twenty-four hours effusion will have taken place in sufficient quantity to be apparent. The signs now denoting the existence of the disease are those due to the effusion. The diagnosis is based upon these signs, in conjunction with the symptoms and history, and on the absence of the signs of pneumonitis.

The signs of effusion are obtained by percussion, auscultation, palpation, and inspection. On percussion, dulness or flatness is found at the base of the chest, extending upward in proportion to the quantity of liquid, the patient being in a sitting posture. By the finger, which serves as a pleximeter, there is also perceived an increased sense of resistance on percussion. The upper limit of the dulness or flatness, the position of the body being vertical, is not on a continuous horizontal line extending over the posterior, lateral, anterior aspects of the chest. In most instances it is higher behind than in front. Prof. G. M. Garland has found that on the posterior aspect the effusion is represented by a curved line resembling the letter *o*.¹ Having ascertained on the anterior aspect of the affected side a point which divides the dulness or flatness below from the resonance above while the patient is sitting, changing the position of the patient to recumbency on the back frequently induces a marked change in the dividing-line between dulness or flatness and the resonance; the liquid gravitating to the posterior part of the chest, the lung descends in front and furnishes resonance for a greater or less distance below the point which was coincident with the level of the liquid while the patient was sitting. This latter test of the presence of liquid is not available in all cases. If the pleural surfaces above the level of the liquid be united by old adhesions or agglutinated by fibrin, the liquid and lung will maintain the same relation in different positions of the body. The failure of this test, therefore, is not proof against the presence of liquid. The test, however, is available in a large majority of cases. The resonance over the lung above the level of the liquid, if the latter rise to a third, a half, or perhaps two-thirds the height of the chest, is increased, and acquires in part a tympanitic quality, constituting vesiculo-tympanitic resonance. That this vesiculo-tympanitic resonance may be due to emphysema of the upper lobe of the lung I have had an opportunity of demonstrating. A hospital case presented the signs of pleuritis with considerable effusion, the vesiculo-tympanitic resonance above the liquid being marked. The patient unexpectedly and suddenly died, and the cause of death was found to be a large thrombus in the left ventricle, the cardiac walls having undergone fatty degeneration. The lower lobe of the lung on the affected side was condensed, and the upper lobe was considerably emphysematous.

[This vesiculo-tympanitic percussion-sound is most marked in the first and second intercostal spaces anteriorly in cases of large effusion. It is known as Skoda's resonance, and is attributed by some authorities to diminished tension of the compressed alveoli—that is, to conditions precisely opposite to those last mentioned.—H.]

On auscultation the respiratory murmur is either suppressed or is feebly appreciable below the level of the liquid. Above the liquid it is usually weak as compared with the murmur on the opposite side. If the lung be considerably reduced in volume by the amount of liquid, the respiratory sound becomes broncho-vesicular and the vocal resonance is increased. If the liquid be sufficient to compress the lung into a solid mass, the latter

¹ Vide *Pneumono-dynamics*, 1878.

furnishes the bronchial respiration. The bronchial respiration is heard over the site of the compressed lung. It is usually limited to that site, but in a certain proportion of cases it is diffused over the greater part or the whole of the affected side. The normal vocal resonance, as a rule, is either suppressed or diminished over that portion of the affected side which corresponds to the space occupied by the liquid; but if the accumulation of liquid be large, bronchophony may be produced either over the compressed lung or the portion in contact with the liquid. The bronchophony has sometimes a tremulous or bleating character, and is then ægophony. If the chest be filled with liquid, bronchophony is sometimes diffused over the whole of the affected side.

[In practising auscultation of the vocal sounds the ear not applied to the chest should be closed, so as to exclude the waves which issue from the patient's mouth. This is a point to which considerable importance is attached by von Ziemssen.—H.]

Vocal fremitus is either arrested or diminished by effusion, as a rule. From this fact is derived valuable evidence of the presence of liquid when the effusion is in the right pleural cavity, in consequence of the greater amount of fremitus over the right side in health. If the question be as to the presence of liquid in the right pleural cavity, and the fremitus be greater on the left than on the right side, the evidence of liquid is strong. There are some rare exceptions to the rule that the vocal resonance and fremitus are either diminished or suppressed over the space occupied by the effusion.¹ [Some of these may be explained by the existence of bands of adhesions that serve as bridges across which the vocal vibrations are conducted to the chest-wall.—H.]

If the quantity of liquid be large enough to distend the pleural sac, the intercostal depressions may be diminished or destroyed at the inferior, anterior, and lateral portions of the chest. This constitutes valuable evidence of the presence of liquid.

Other and marked signs of effusion are present if the quantity of liquid be sufficient to dilate the chest. This occurs exceptionally in acute pleuritis. It occurs much oftener in the chronic variety of the disease, and the signs referred to will be noticed in connection with the diagnosis of the latter.

The physical signs not only lead to a positive diagnosis after the first stage, but they show the amount of liquid in the pleural sac—a point of importance with reference to treatment. By means of daily explorations the physician is able to ascertain whether the effusion be increasing or diminishing, and the rate of either the increase or diminution. The information thus obtained is highly important as a guide in the employment of therapeutical measures. This information cannot be obtained from the symptoms. The signs, therefore, are essential not only to the diagnosis, but to a proper knowledge of the progress of the disease.

After absorption, to a greater or less extent, of the liquid, the pleural surfaces coming into contact over a larger area, and roughened by fibrin which has now become dense and closely adherent, a friction murmur is frequently produced. This is sometimes so loud as to be heard by the patient. It may continue into convalescence, ceasing when the pleural surfaces have become united by means of newly-formed tissue. A friction murmur, however, by no means occurs invariably, even at this stage of the disease.

The occasional occurrence of a pleural, cardiac friction sound in cases of pleuritis affecting the left side is to be borne in mind. The movements of

¹ Vide article by the author, entitled "Large Pleuritic Effusion in the Right Side, without Notable Diminution of Vocal Resonance and Fremitus," *Am. Journ. of Med. Science*, April, 1882.

the heart sometimes occasion a rubbing of pleural surfaces sufficiently to cause a sound which, having the cardiac rhythm and being heard when breathing is suspended, may seem to denote pericarditis. The sound is limited to the left border of the heart, and pericardial effusion is of course wanting. Pericarditis, when this sign is present, it must be confessed, is not as easily excluded. An error of diagnosis in this regard is more likely to occur from the fact that this disease is not a very infrequent complication of pleuritis.

[This pleuro-pericardial friction may be recognized by the fact that it diminishes in intensity or ceases entirely when the breathing is suspended. It is also, as a rule, loudest over the apex of the heart or limited to this region, while the friction-murmur caused by pericarditis is loudest over the base of the heart.—H.]

PROGNOSIS.—The prognosis in cases of acute primary or idiopathic simple pleuritis is always favorable, provided the disease be uncomplicated and the constitution of the patient be not enfeebled. Without any therapeutical interference it would very rarely prove fatal. I have collected several cases in which the disease passed through its course favorably without any treatment. It may possibly prove fatal in consequence of a large amount of effusion occurring very rapidly, death taking place by apnoea, produced, probably, by congestion of the lung on the unaffected side (collateral fluxion), in addition to the loss of function of the lung on the affected side from compression by the liquid. I have known an instance in which the death of a hospital patient suddenly and unexpectedly seemed fairly attributable to the fact that the pleural sac was greatly distended with rapidly-effused liquid. Developed as a sequel to other diseases, or in the course of a grave affection, or in persons with broken constitutions, it may destroy life by asthenia. Acute pericarditis is sometimes developed simultaneously with, or during the progress of, pleuritis, and these associated diseases are liable to prove fatal. Their occasional coincidence is to be borne in mind, or the pericarditis in this connection, if not carefully sought for, will be likely to be overlooked. As already stated, the development of pneumonitis consecutive to pleuritis is not to be expected, nor is there much danger that an acute simple pleuritis, after its development, will eventuate in suppuration, constituting the variety of the disease called empyema. In short, the intrinsic tendency of the disease is to recovery, a fatal termination being due very rarely to the disease *per se*, but to affections with which it may be associated.

CHAPTER II.

ACUTE PLEURITIS (CONTINUED).

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The Use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and Third Stages of Acute Pleuritis.

THE objects of treatment in acute pleuritis differ in its different stages, and the latter therefore claim, severally, distinct consideration with reference to therapeutic indications. The objects in the first stage are to arrest,

if possible, the progress of the disease, to diminish its intensity, if it be not arrested, to limit the amount of morbid products, and to relieve suffering; in other words, the treatment relates to the employment of abortive, curative, and palliative measures. The indications in the first stage of this disease are essentially the same as in the early period of most acute inflammations. The general principles which should govern the treatment in this stage, therefore, will be here considered, and simply referred to hereafter in connection with other diseases to which they are measurably applicable.

Owing to its brief duration, patients are frequently not seen until the first stage has passed. Can the disease be arrested at this stage if the opportunity offer and a positive diagnosis be made? Admitting that physicians formerly did sometimes succeed, as they believed, in cutting short the disease, it must be said in answer to this question that there are no known abortive means which can be relied upon. Bloodletting and other so-called antiphlogistic measures formerly employed for this object have certainly not been successful in a sufficient number of cases to warrant their employment to an extent which will render them likely to do harm if they be not successful. Assuming that the disease goes on to the second stage, the question then is, What curative and palliative measures are to be employed? This question leads at once to the consideration of bloodletting.

A great change has taken place with respect to bloodletting in the treatment of acute inflammations. This measure was formerly thought to be highly important, and was rarely omitted. It is now considered by many as seldom, if ever, called for. The infrequent use of the lancet now, contrasted with its frequent use forty years ago, constitutes one of the most striking of the changes in the practice of medicine which have occurred during this period. It can hardly be doubted that this measure was formerly adopted too indiscriminately, and often employed too largely; but the natural tendency being to pass from one extreme to another, the utility of bloodletting in certain cases at the present time is perhaps not sufficiently appreciated.

Experience and pathological reasoning combine to show that bloodletting rarely has a direct controlling effect upon an inflammatory disease. It may exert a powerful immediate effect as a palliative measure, but whatever curative power it may possess is exerted indirectly. Its therapeutic action in general consists in lessening the frequency and force of the heart's action, and diminishing arterial tension and the intensity of pyrexia. In the early period of an acute inflammation accompanied by notable pyrexia and arterial tension the abstraction of blood affords relief, and may contribute to a favorable progress of the disease. It should enter into the treatment of a certain proportion of cases, provided other and more conservative means for the same ends were not available.

The evils of bloodletting arise from its spoliative effect upon the blood. It diminishes the red globules, and these, during the progress of an acute disease, are not readily reproduced. It induces thus the anæmic condition, and in this way impairs the vital powers. It will be likely to do harm, therefore, whenever it is important to economize the powers of life, and it may contribute to a fatal result in diseases or cases of disease which involve danger of death by asthenia.

The useful effects of bloodletting may frequently, if not generally, be obtained by other means which require less circumspection in their employment, because if injudiciously resorted to they are in a less degree hurtful. The mass of blood may be temporarily lessened by saline purgatives and diaphoretic remedies, conjoined with a restricted ingestion of food and liquids. Depletion is obtained in this way without impoverishment of the blood. The frequency and force of the heart's action may be affected by nauseant seda-

tives, such as tartar emetic, ipecacuanha, etc., and by direct sedatives—namely, digitalis, aconite, and the veratrum viride. By antipyretic remedies and measures for the abstraction of heat the pyrexia may be lessened without the expenditure of blood, and thus the evils of bloodletting be avoided. The advantage of bloodletting consists mainly in the promptness of its operation. Several hours are required to secure results from the means employed in lieu of bloodletting, whereas the effects of the latter are produced in a few moments.

In accordance with these views, bloodletting is never indicated by the fact simply that acute inflammation exists; it is a measure directed not to the disease *per se*, but to circumstances associated with the disease. The state of the circulation and other circumstances furnish the indications for the employment of this measure. It may be admissible if, with the development of inflammation, there exist notable pyrexia, the patient being robust and in good health when attacked, and the disease not involving danger of death by asthenia. The measure is admissible, under the conditions just stated, whenever the promptness with which its effects are obtained renders it desirable to adopt it in preference to other measures producing the same effects with more or less delay. *Per contra*, bloodletting is not admissible when the development of inflammation is not accompanied by notable pyrexia, when the patient was not in good health when attacked, when the constitution is feeble, and when the disease involves danger of death by asthenia. These rules of practice, while they accord to bloodletting therapeutic value, undoubtedly restrict its use within narrow limits.

Applying these rules to the disease under consideration, a patient in the first stage of acute pleuritis, robust, suffering from severe pain and dyspnoea, with high fever, the pulse moderately accelerated and not weak, will derive immediate relief from the abstraction of from ten to sixteen ounces of blood. The loss of this quantity of blood under such circumstances in a disease like this, which does not tend to destroy life by asthenia, will give rise to no evil results, but will be likely to affect favorably the progress of the disease. On the other hand, a patient feeble or anæmic, with a pulse more or less frequent, but denoting diminished power of the heart's action, should not be bled, notwithstanding the local symptoms would undoubtedly be thereby relieved. By impairing the vital powers the loss of blood will do harm, and is not admissible under these circumstances merely as a palliative remedy. And in the first case, if the local symptoms do not urgently call for immediate relief, other measures may be substituted for the bloodletting. It may be added that, aside from the immediate relief afforded in acute pleuritis by bloodletting, it has been theoretically considered as preventing, in a measure, fibrinous exudation by lessening arterial tension.

Before leaving the consideration of bloodletting several incidental points may be briefly noticed.

This measure is perhaps more applicable to the treatment of inflammation affecting the pulmonary organs than to the treatment of other inflammatory affections, in consequence of the relations of the former to the circulation. The free passage of the blood through the pulmonary circuit seems to be promoted, and the functional labor which the lungs have to perform is diminished by the abstraction of blood. At all events, relief of the pain and dyspnoea attendant on the early stage of acute inflammation of any of the pulmonary structures is more quickly and effectually procured by bloodletting than by other measures. Were it not for its ulterior effects, it would be invaluable as a palliative measure in pleuritis and other inflammatory affections within the chest.

In another mode the abstraction of blood may sometimes be peculiarly use-

ful in affections of the lungs involving considerable or great obstruction to the passage of blood through the pulmonary circuit. This obstruction occasions an accumulation of blood within the cavities of the right side of the heart; hence there is congestion of the systemic veins, giving rise, if sufficient in degree, to lividity or cyanosis. The accumulation of blood in the cavities of the right side of the heart under these circumstances weakens the force with which the ventricle and auricle contract, and paralysis of this portion of the heart from over-distension may follow. The formation of a heart-clot may be a consequence of this accumulation. In certain cases bloodletting may be advisable with a view to diminish the accumulation of blood in the cavities of the right side of the heart; but it is to be employed for that end only when the contraindications which have been mentioned are not present.

After bloodletting, the pulse sometimes appears to indicate increased power of the heart's action. The artery seems to strike against the finger with more force than before the abstraction of blood. Formerly, practitioners were misled by this effect upon the pulse, and bloodletting was employed as a means of increasing the power of the heart's action. The sensation which the finger receives in these cases is delusive, and is caused by the quickness of the movements of the artery. This has been shown by the sphymograph to depend on the diminished tension of the arteries following the abstraction of blood. It is to be borne in mind, in estimating the power of the heart's action by the sensible characters of the pulse, that the sense of resistance which is felt and the amount of pressure required to compress the artery are the evidences of strength.

To a certain extent the advantages of bloodletting, inclusive of the promptness of its operation, may be obtained by arresting temporarily or retarding the circulation in a part more or less remote from the seat of the inflammation. A ligature applied to one or more of the extremities will effect this object; so also will the removal of atmospheric pressure over a considerable space. There is reason to think that these measures as substitutes for bloodletting have not been sufficiently considered. It is probably owing to their effect in withdrawing temporarily a certain quantity of blood from the circulation that dry cups and various so-called revulsive applications to the surface of the body are of utility in the first stage of acute inflammation. A considerable number of dry cups applied to the chest constitute an efficient substitute for bloodletting, often affording promptly notable relief of pain and dyspnœa.

The evils of indiscriminate and excessive bloodletting are manifested by a larger rate of mortality in those diseases which tend to destroy life by asthenia, and it can hardly be doubted that the death-rate has been diminished by a much more sparing use of the lancet within late years. But the results of injudicious bloodletting are manifested in cases which end in recovery as well as in those which end fatally. These results consist in protracted convalescence and subsequent feebleness. The cases of different inflammations treated formerly by bloodletting, together with other measures entering into the so-called antiphlogistic method, and the cases now treated otherwise, present a striking contrast as regards the condition of patients during convalescence and after recovery.

The opinion is held by some that diseases have undergone a notable change of type. They who hold this opinion suppose that bloodletting and other antiphlogistic measures are less appropriate now than formerly, in consequence of such a change. With a professional experience of over fifty years, I do not hesitate to express a conviction that acute inflammations at the present day are essentially the same as they were as far back as the time just named,

the heart sometimes occasion a rubbing of pleural surfaces sufficiently to cause a sound which, having the cardiac rhythm and being heard when breathing is suspended, may seem to denote pericarditis. The sound is limited to the left border of the heart, and pericardial effusion is of course wanting. Pericarditis, when this sign is present, it must be confessed, is not at once easily excluded. An error of diagnosis in this regard is more likely to occur from the fact that this disease is not a very infrequent complication of pleuritis.

[This pleuro-pericardial friction may be recognized by the fact that it diminishes in intensity or ceases entirely when the breathing is suspended. It is also, as a rule, loudest over the apex of the heart or limited to this region, while the friction-murmur caused by pericarditis is loudest over the base of the heart.—H.]

PROGNOSIS.—The prognosis in cases of acute primary or idiopathic simple pleuritis is always favorable, provided the disease be uncomplicated and the constitution of the patient be not enfeebled. Without any therapeutical interference it would very rarely prove fatal. I have collected several cases in which the disease passed through its course favorably without any treatment. It may possibly prove fatal in consequence of a large amount of effusion occurring very rapidly, death taking place by apnœa, produced, probably, by congestion of the lung on the unaffected side (collateral fluxion), in addition to the loss of function of the lung on the affected side from compression by the liquid. I have known an instance in which the death of a hospital patient suddenly and unexpectedly seemed fairly attributable to the fact that the pleural sac was greatly distended with rapidly-effused liquid. In short, the intrinsic tendency of the disease is to recovery, a fatal termination being due very rarely to the disease *per se*, but to affections with which it may be associated.

CHAPTER II.

ACUTE PLEURITIS (CONTINUED).

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The Use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and Third Stages of Acute Pleuritis.

THE objects of treatment in acute pleuritis differ in its different stages, and the latter therefore claim, severally, distinct consideration with reference to therapeutic indications. The objects in the first stage are to arrest,

if possible, the progress of the disease, to diminish its intensity, if it be not arrested, to limit the amount of morbid products, and to relieve suffering; in other words, the treatment relates to the employment of abortive, curative, and palliative measures. The indications in the first stage of this disease are essentially the same as in the early period of most acute inflammations. The general principles which should govern the treatment in this stage, therefore, will be here considered, and simply referred to hereafter in connection with other diseases to which they are measurably applicable.

Owing to its brief duration, patients are frequently not seen until the first stage has passed. Can the disease be arrested at this stage if the opportunity offer and a positive diagnosis be made? Admitting that physicians formerly did sometimes succeed, as they believed, in cutting short the disease, it must be said in answer to this question that there are no known abortive means which can be relied upon. Bloodletting and other so-called antiphlogistic measures formerly employed for this object have certainly not been successful in a sufficient number of cases to warrant their employment to an extent which will render them likely to do harm if they be not successful. Assuming that the disease goes on to the second stage, the question then is, What curative and palliative measures are to be employed? This question leads at once to the consideration of bloodletting.

A great change has taken place with respect to bloodletting in the treatment of acute inflammations. This measure was formerly thought to be highly important, and was rarely omitted. It is now considered by many as seldom, if ever, called for. The infrequent use of the lancet now, contrasted with its frequent use forty years ago, constitutes one of the most striking of the changes in the practice of medicine which have occurred during this period. It can hardly be doubted that this measure was formerly adopted too indiscriminately, and often employed too largely; but the natural tendency being to pass from one extreme to another, the utility of bloodletting in certain cases at the present time is perhaps not sufficiently appreciated.

Experience and pathological reasoning combine to show that bloodletting rarely has a direct controlling effect upon an inflammatory disease. It may exert a powerful immediate effect as a palliative measure, but whatever curative power it may possess is exerted indirectly. Its therapeutic action in general consists in lessening the frequency and force of the heart's action, and diminishing arterial tension and the intensity of pyrexia. In the early period of an acute inflammation accompanied by notable pyrexia and arterial tension the abstraction of blood affords relief, and may contribute to a favorable progress of the disease. It should enter into the treatment of a certain proportion of cases, provided other and more conservative means for the same ends were not available.

The evils of bloodletting arise from its spoliative effect upon the blood. It diminishes the red globules, and these, during the progress of an acute disease, are not readily reproduced. It induces thus the anæmic condition, and in this way impairs the vital powers. It will be likely to do harm, therefore, whenever it is important to economize the powers of life, and it may contribute to a fatal result in diseases or cases of disease which involve danger of death by asthenia.

The useful effects of bloodletting may frequently, if not generally, be obtained by other means which require less circumspection in their employment, because if injudiciously resorted to they are in a less degree hurtful. The mass of blood may be temporarily lessened by saline purgatives and diaphoretic remedies, conjoined with a restricted ingestion of food and liquids. Depletion is obtained in this way without impoverishment of the blood. The frequency and force of the heart's action may be affected by nauseant seda-

tives, such as tartar emetic, ipecacuanha, etc., and by direct sedatives—namely, digitalis, aconite, and the veratrum viride. By antipyretic remedies and measures for the abstraction of heat the pyrexia may be lessened without the expenditure of blood, and thus the evils of bloodletting be avoided. The advantage of bloodletting consists mainly in the promptness of its operation. Several hours are required to secure results from the means employed in lieu of bloodletting, whereas the effects of the latter are produced in a few moments.

In accordance with these views, bloodletting is never indicated by the fact simply that acute inflammation exists; it is a measure directed not to the disease *per se*, but to circumstances associated with the disease. The state of the circulation and other circumstances furnish the indications for the employment of this measure. It may be admissible if, with the development of inflammation, there exist notable pyrexia, the patient being robust and in good health when attacked, and the disease not involving danger of death by asthenia. The measure is admissible, under the conditions just stated, whenever the promptness with which its effects are obtained renders it desirable to adopt it in preference to other measures producing the same effects with more or less delay. *Per contra*, bloodletting is not admissible when the development of inflammation is not accompanied by notable pyrexia, when the patient was not in good health when attacked, when the constitution is feeble, and when the disease involves danger of death by asthenia. These rules of practice, while they accord to bloodletting therapeutic value, undoubtedly restrict its use within narrow limits.

Applying these rules to the disease under consideration, a patient in the first stage of acute pleuritis, robust, suffering from severe pain and dyspnoea, with high fever, the pulse moderately accelerated and not weak, will derive immediate relief from the abstraction of from ten to sixteen ounces of blood. The loss of this quantity of blood under such circumstances in a disease like this, which does not tend to destroy life by asthenia, will give rise to no evil results, but will be likely to affect favorably the progress of the disease. On the other hand, a patient feeble or anæmic, with a pulse more or less frequent, but denoting diminished power of the heart's action, should not be bled, notwithstanding the local symptoms would undoubtedly be thereby relieved. By impairing the vital powers the loss of blood will do harm, and is not admissible under these circumstances merely as a palliative remedy. And in the first case, if the local symptoms do not urgently call for immediate relief, other measures may be substituted for the bloodletting. It may be added that, aside from the immediate relief afforded in acute pleuritis by bloodletting, it has been theoretically considered as preventing, in a measure, fibrinous exudation by lessening arterial tension.

Before leaving the consideration of bloodletting several incidental points may be briefly noticed.

This measure is perhaps more applicable to the treatment of inflammation affecting the pulmonary organs than to the treatment of other inflammatory affections, in consequence of the relations of the former to the circulation. The free passage of the blood through the pulmonary circuit seems to be promoted, and the functional labor which the lungs have to perform is diminished by the abstraction of blood. At all events, relief of the pain and dyspnoea attendant on the early stage of acute inflammation of any of the pulmonary structures is more quickly and effectually procured by bloodletting than by other measures. Were it not for its ulterior effects, it would be invaluable as a palliative measure in pleuritis and other inflammatory affections within the chest.

In another mode the abstraction of blood may sometimes be peculiarly use-

ful in affections of the lungs involving considerable or great obstruction to the passage of blood through the pulmonary circuit. This obstruction occasions an accumulation of blood within the cavities of the right side of the heart; hence there is congestion of the systemic veins, giving rise, if sufficient in degree, to lividity or cyanosis. The accumulation of blood in the cavities of the right side of the heart under these circumstances weakens the force with which the ventricle and auricle contract, and paralysis of this portion of the heart from over-distension may follow. The formation of a heart-clot may be a consequence of this accumulation. In certain cases bloodletting may be advisable with a view to diminish the accumulation of blood in the cavities of the right side of the heart; but it is to be employed for that end only when the contraindications which have been mentioned are not present.

After bloodletting, the pulse sometimes appears to indicate increased power of the heart's action. The artery seems to strike against the finger with more force than before the abstraction of blood. Formerly, practitioners were misled by this effect upon the pulse, and bloodletting was employed as a means of increasing the power of the heart's action. The sensation which the finger receives in these cases is delusive, and is caused by the quickness of the movements of the artery. This has been shown by the sphymograph to depend on the diminished tension of the arteries following the abstraction of blood. It is to be borne in mind, in estimating the power of the heart's action by the sensible characters of the pulse, that the sense of resistance which is felt and the amount of pressure required to compress the artery are the evidences of strength.

To a certain extent the advantages of bloodletting, inclusive of the promptness of its operation, may be obtained by arresting temporarily or retarding the circulation in a part more or less remote from the seat of the inflammation. A ligature applied to one or more of the extremities will effect this object; so also will the removal of atmospheric pressure over a considerable space. There is reason to think that these measures as substitutes for bloodletting have not been sufficiently considered. It is probably owing to their effect in withdrawing temporarily a certain quantity of blood from the circulation that dry cups and various so-called revulsive applications to the surface of the body are of utility in the first stage of acute inflammation. A considerable number of dry cups applied to the chest constitute an efficient substitute for bloodletting, often affording promptly notable relief of pain and dyspnoea.

The evils of indiscriminate and excessive bloodletting are manifested by a larger rate of mortality in those diseases which tend to destroy life by asthenia, and it can hardly be doubted that the death-rate has been diminished by a much more sparing use of the lancet within late years. But the results of injudicious bloodletting are manifested in cases which end in recovery as well as in those which end fatally. These results consist in protracted convalescence and subsequent feebleness. The cases of different inflammations treated formerly by bloodletting, together with other measures entering into the so-called antiphlogistic method, and the cases now treated otherwise, present a striking contrast as regards the condition of patients during convalescence and after recovery.

The opinion is held by some that diseases have undergone a notable change of type. They who hold this opinion suppose that bloodletting and other antiphlogistic measures are less appropriate now than formerly, in consequence of such a change. With a professional experience of over fifty years, I do not hesitate to express a conviction that acute inflammations at the present day are essentially the same as they were as far back as the time just named,

and that antiphlogistic measures were neither more nor less appropriate than now.

In addition to general bloodletting or the employment of venesection, much importance was formerly attached to the abstraction of blood by cups or leeches applied in the neighborhood of the inflamed part. Local bloodletting in some cases is more convenient than venesection; but, so far as the abstraction of blood is concerned, it is difficult to conceive that it is a matter of much importance from what part of the body or vascular system it is taken. Whether it be abstracted by means of cups, leeches, or the lancet, the benefit or injury will depend on the quantity withdrawn in a given period. Whatever advantage may accrue from the removal of a certain amount of blood by cups or leeches over the extraction of the same amount by venesection must be derived from the operation of the former as a revulsive measure.

With these remarks, leaving the consideration of bloodletting, and reverting to the question concerning the curative and palliative measures to be employed in the first stage of acute pleuritis, we are led to the consideration of opium. And with respect to this remedy certain considerations may here be presented which will apply to the treatment of other inflammations.

A great change has taken place with respect to the use of opium in acute inflammations. It was formerly used with much reserve, under the apprehension that, acting as a stimulant, its influence upon the local disease must be unfavorable. It was regarded as antagonistic to the antiphlogistic plan of treatment. Clinical experience and sounder pathological views, however, have led to the knowledge of its great value in the treatment of inflammatory affections wherever situated. It is valuable, not alone as a palliative but as a curative remedy. Its palliative efficacy is of course intelligible, and we can also to some extent understand its curative influence. By relieving pain it diminishes the determination of blood to the inflamed part; for pain is alone sufficient to occasion an increased afflux of blood to a part. This fact is illustrated by cases of neuralgia affecting a superficial nerve. Neuralgia of the supraorbital nerve, for example, occasions a determination of blood to the conjunctiva, so that this membrane appears to be inflamed, and the congestion disappears as soon as the pain is relieved by a full opiate. Opium exerts also a curative influence by preventing or diminishing the constitutional disturbance which inflammations are apt to occasion; it places the system in a condition to tolerate better the local affection. The severity of an inflammatory disease depends much on the amount of constitutional disturbance which it occasions; and with respect to the latter different cases differ widely, although in each the degree and extent of the local affection be the same. Life is often destroyed, not in consequence of the injury done to the inflamed part, but because the vital powers are inadequate to bear the continuance of the disease. These considerations afford some insight into the utility of opium, especially when patients are able to take this remedy without inconvenience, there being, as is well known, a great difference among different persons in this regard. The evidence of the curative value of opium, of course, is derived from experience, and there is ample ground for the belief that by its judicious use in acute inflammations not only is their course divested of much of the suffering which would otherwise be experienced, but their intensity is lessened, and the danger of death diminished in those inflammations which tend to destroy life by asthenia. The immediate effect of this remedy is often very strikingly manifest in improvement as regards the local and general symptoms.

Considering, now, the use of opium in the first stage of acute pleuritis after the abstraction of blood, if this be deemed advisable, or after a saline purgative, if this be employed in lieu of bloodletting, it will generally be

judicious to prescribe opium,¹ in some form, in doses sufficient to relieve pain and place the system fairly under an anodyne influence. If the pain be severe and the constitutional disturbance considerable, the use of opium need not be delayed for the operation of a purgative, but may be at once entered upon. This is perhaps the most judicious course in the majority of cases, a purgative being deferred until a distinct anodyne impression has been produced and maintained for some hours by opium. Conjoined with the use of opium, sedative remedies, addressed to the circulation, may be employed. These should not be pushed to the extent of producing disorder. If, for example, tartar emetic be given, it should not be carried beyond the point of slight nausea, and the veratrum viride, if given, should occasion no appreciable effects beyond a reduction of the frequency of the heart's action. These remedies, it is to be borne in mind, are addressed, not to the disease *per se*, but to the symptomatic phenomena of the disease.

Aconite is a valuable sedative remedy in the early stage of this as of other acute inflammations. The most effective mode of administration in order to secure promptly and fully its remedial effect is that recommended by Ringer—namely, half a drop or a drop of the tincture to be given every ten minutes or quarter of an hour for two hours, and afterward the dose repeated hourly. Smaller doses are to be given if the pulse become feeble or there be much prostration.

A summary of the treatment of the first stage of acute pleuritis, then, will embrace bloodletting in some cases, the use of opium given sufficiently to relieve pain and tranquillize the system, a saline purgative, and remedies designed to act as sedatives upon the circulation. Blisters should not be applied in this stage. They occasion general disturbance more than enough to counterbalance any effect by way of revulsion. They add an inflammation of the skin to the existing inflammation of the pleura. A sinapism, turpentine stupes, or fomentations to the chest will secure all the benefit of vesication without the annoyance and other evils of the latter. Moreover, a blister is an obstacle in the way of those examinations of the chest which are of importance as affording the only reliable information respecting the progress of the disease. The employment of cold in the form of the bath, the wet sheet, or sponging the body, and other antipyretic measures, are rarely called for in this disease, inasmuch as a high temperature (hyperpyrexia) is of exceptional occurrence. These measures, however, are indicated if the body-heat rise to 104° or 105°, as occurs in the so-called pleuritis acutissima.

The application of cold to the affected side by means of the ice-bladder or by napkins dipped in ice-water and renewed every five minutes is a safe and efficient measure for the relief of pain. Theoretically, the application of cold for a local effect may be considered to be useful by causing contraction of the vessels and thereby lessening inflammatory exudation.

Preventing the respiratory movements of the chest on the affected side, by means of long strips of adhesive plaster encircling this side and extending partially over the side not affected, affords notable relief of the lancinating pain felt in the acts of inspiration.

In the second stage, so long as the quantity of effusion is small and a further accumulation may be expected to take place, the indications belonging to the first stage may continue. If the pain be still acute and the fever have not abated, measures to relieve the former and lessen the latter are indicated. Bloodletting is rarely called for, but depletion by purgatives may be useful, not only by lessening fever, but by restraining the amount

¹ The word "opium" is here used as a general term, including the alkaloids, morphia and codeia.

and that antiphlogistic measures were neither more nor less appropriate then than now.

In addition to general bloodletting or the employment of venesection, much importance was formerly attached to the abstraction of blood by cups or leeches applied in the neighborhood of the inflamed part. Local bloodletting in some cases is more convenient than venesection; but, so far as the abstraction of blood is concerned, it is difficult to conceive that it is a matter of much importance from what part of the body or vascular system it is taken. Whether it be abstracted by means of cups, leeches, or the lancet, the benefit or injury will depend on the quantity withdrawn in a given period. Whatever advantage may accrue from the removal of a certain amount of blood by cups or leeches over the extraction of the same amount by venesection must be derived from the operation of the former as a revulsive measure.

With these remarks, leaving the consideration of bloodletting, and reverting to the question concerning the curative and palliative measures to be employed in the first stage of acute pleuritis, we are led to the consideration of opium. And with respect to this remedy certain considerations may here be presented which will apply to the treatment of other inflammations.

A great change has taken place with respect to the use of opium in acute inflammations. It was formerly used with much reserve, under the apprehension that, acting as a stimulant, its influence upon the local disease must be unfavorable. It was regarded as antagonistic to the antiphlogistic plan of treatment. Clinical experience and sounder pathological views, however, have led to the knowledge of its great value in the treatment of inflammatory affections wherever situated. It is valuable, not alone as a palliative but as a curative remedy. Its palliative efficacy is of course intelligible, and we can also to some extent understand its curative influence. By relieving pain it diminishes the determination of blood to the inflamed part; for pain is alone sufficient to occasion an increased afflux of blood to a part. This fact is illustrated by cases of neuralgia affecting a superficial nerve. Neuralgia of the supraorbital nerve, for example, occasions a determination of blood to the conjunctiva, so that this membrane appears to be inflamed, and the congestion disappears as soon as the pain is relieved by a full opiate. Opium exerts also a curative influence by preventing or diminishing the constitutional disturbance which inflammations are apt to occasion; it places the system in a condition to tolerate better the local affection. The severity of an inflammatory disease depends much on the amount of constitutional disturbance which it occasions; and with respect to the latter different cases differ widely, although in each the degree and extent of the local affection be the same. Life is often destroyed, not in consequence of the injury done to the inflamed part, but because the vital powers are inadequate to bear the continuance of the disease. These considerations afford some insight into the utility of opium, especially when patients are able to take this remedy without inconvenience, there being, as is well known, a great difference among different persons in this regard. The evidence of the curative value of opium, of course, is derived from experience, and there is ample ground for the belief that by its judicious use in acute inflammations not only is their course divested of much of the suffering which would otherwise be experienced, but their intensity is lessened, and the danger of death diminished in those inflammations which tend to destroy life by asthenia. The immediate effect of this remedy is often very strikingly manifest in improvement as regards the local and general symptoms.

Considering, now, the use of opium in the first stage of acute pleuritis after the abstraction of blood, if this be deemed advisable, or after a saline purgative, if this be employed in lieu of bloodletting, it will generally be

judicious to prescribe opium,¹ in some form, in doses sufficient to relieve pain and place the system fairly under an anodyne influence. If the pain be severe and the constitutional disturbance considerable, the use of opium need not be delayed for the operation of a purgative, but may be at once entered upon. This is perhaps the most judicious course in the majority of cases, a purgative being deferred until a distinct anodyne impression has been produced and maintained for some hours by opium. Conjoined with the use of opium, sedative remedies, addressed to the circulation, may be employed. These should not be pushed to the extent of producing disorder. If, for example, tartar emetic be given, it should not be carried beyond the point of slight nausea, and the veratrum viride, if given, should occasion no appreciable effects beyond a reduction of the frequency of the heart's action. These remedies, it is to be borne in mind, are addressed, not to the disease *per se*, but to the symptomatic phenomena of the disease.

Aconite is a valuable sedative remedy in the early stage of this as of other acute inflammations. The most effective mode of administration in order to secure promptly and fully its remedial effect is that recommended by Ringer—namely, half a drop or a drop of the tincture to be given every ten minutes or quarter of an hour for two hours, and afterward the dose repeated hourly. Smaller doses are to be given if the pulse become feeble or there be much prostration.

A summary of the treatment of the first stage of acute pleuritis, then, will embrace bloodletting in some cases, the use of opium given sufficiently to relieve pain and tranquillize the system, a saline purgative, and remedies designed to act as sedatives upon the circulation. Blisters should not be applied in this stage. They occasion general disturbance more than enough to counterbalance any effect by way of revulsion. They add an inflammation of the skin to the existing inflammation of the pleura. A sinapism, turpentine stupes, or fomentations to the chest will secure all the benefit of vesication without the annoyance and other evils of the latter. Moreover, a blister is an obstacle in the way of those examinations of the chest which are of importance as affording the only reliable information respecting the progress of the disease. The employment of cold in the form of the bath, the wet sheet, or sponging the body, and other antipyretic measures, are rarely called for in this disease, inasmuch as a high temperature (hyperpyrexia) is of exceptional occurrence. These measures, however, are indicated if the body-heat rise to 104° or 105°, as occurs in the so-called pleuritis acutissima.

The application of cold to the affected side by means of the ice-bladder or by napkins dipped in ice-water and renewed every five minutes is a safe and efficient measure for the relief of pain. Theoretically, the application of cold for a local effect may be considered to be useful by causing contraction of the vessels and thereby lessening inflammatory exudation.

Preventing the respiratory movements of the chest on the affected side, by means of long strips of adhesive plaster encircling this side and extending partially over the side not affected, affords notable relief of the lancinating pain felt in the acts of inspiration.

In the second stage, so long as the quantity of effusion is small and a further accumulation may be expected to take place, the indications belonging to the first stage may continue. If the pain be still acute and the fever have not abated, measures to relieve the former and lessen the latter are indicated. Bloodletting is rarely called for, but depletion by purgatives may be useful, not only by lessening fever, but by restraining the amount

¹ The word "opium" is here used as a general term, including the alkaloids, morphia and codeia.

of effusion. Diaphoretic remedies are useful by contributing to the two ends just stated. Opium is indicated in proportion to the pain and constitutional disturbance, and sedative remedies addressed to the circulation may be employed.

These measures cease to be appropriate when considerable effusion of liquid has taken place, when pain is no longer a prominent symptom, and when the pyrexia has either ceased or become much diminished. The object of treatment now is to promote absorption of the effused liquid. The means which may be employed for this object are hydragogue purgatives, diuretics, blisters, and the use of certain remedies which have been supposed to act directly as sorbefacients.

Hydragogue purgatives act most promptly and efficiently. The more active hydragogues, which are drastic in their operation, should be given circum-spectly, and generally need not be employed. Reference is had to such remedies as elaterium and gamboge. The saline purgatives, such as the bitartrate of potassa, either alone or in combination with jalap (*pulvis purgans*), the citrate or the sulphate of magnesia, are to be preferred as sufficiently effective and less severe.

[The last-mentioned drug is best administered after the method of Hay: From half an ounce to an ounce and a half of Epsom salts should be given every morning before breakfast, the drug being dissolved in the least possible amount of water. The effect of such doses is to cause profuse watery discharges, and under their use effusions sometimes disappear with remarkable rapidity. They should, however, only be administered to comparatively robust patients, since they act by draining away large quantities of serum and are equivalent to a species of depletion.—H.]

Diuretics are sometimes equally but less rapidly effective. They effect the object with less perturbation and are less debilitating. The union of two or more diuretic remedies is more likely to prove effective than a single remedy of this class. Half an ounce of the infusion of digitalis, freshly made, given three or four times daily, and either the bitartrate or the acetate of potassa given in addition, form a combination which is often efficient.

[The surest and most powerful diaphoretic is undoubtedly *jaborandi*, which may be given either in the form of infusion or fluid extract; or, better still, the alkaloid pilocarpine, in the form of the nitrate or hydrochlorate, may be injected beneath the skin. These substances are, however, decidedly depressing, and should never be administered to weakly individuals.—H.]

Restriction in the amount of fluids ingested is an important point with reference to absorption. The elimination of water by the bowels or kidneys is of little avail if the patient be allowed to take as much into the system as is eliminated. The quantity should be as small as is compatible with comfort.

Blisters in this stage of the disease doubtless contribute to the object under consideration. If other means be effective, however, they may be dispensed with. Their interference with examinations of the chest is a matter of considerable consequence, and the annoyance which they frequently occasion is not an inconsiderable objection. If employed, small blisters successively applied in different situations, removed as soon as vesication commences, the vesicated surfaces being allowed to dry up rapidly, accomplish all the good to be effected in this way, with the smallest amount of inconvenience both to the physician and patient.

Remedies which have been supposed to act as sorbefacients are mercury and iodine. Mercury I have long ceased to employ in this disease. Of doubtful efficacy, the annoyance and other evils incident to mercurialization render it objectionable. The efficacy of iodine is perhaps equally doubtful,

but it is not open to similar objections. It may be given internally or applied externally in the form of either the ointment or tincture.

[Marked success often attends the treatment of pleurisy with the salicyl compounds, many cases of the disease being, as previously stated, of rheumatic origin. The sodium salicylate may be given in divided doses to the extent of from 1 to 2 drachms in the twenty-four hours. The chief objection to this drug is that it is decidedly nauseous to many individuals, but this may sometimes be obviated by administering it in pill or capsule.—H.]

It is an important injunction not to continue perturbatory measures with a view to promote absorption too long nor too push their use too far. The decrease of effusion after it has reached a certain point is likely to go on slowly, for reasons already stated. Whenever this point is reached, cathartics and diuretics should be discontinued or employed with great moderation, else they will be likely to do harm rather than good, by weakening the patient; and if at any time these measures appear to impair the general condition, the propriety of continuing them is doubtful. A leading object in the second stage of the disease is to maintain the constitutional strength. For this object the diet should be nutritious; tonic remedies are useful, and a little wine or spirit may be allowed. These measures should constitute the treatment after those designed to promote absorption have been sufficiently carried out, and should take the place of the latter whenever there is evidence of the strength giving way.

It is very rarely the case that this disease tends to a fatal ending by asthenia. Should such a tendency be manifested by the symptoms—namely, frequency and feebleness of the pulse, muscular prostration, etc.—the measures which constitute the supporting treatment are of course indicated. These measures, which form the most important part of the treatment of the diseases involving danger by asthenia, consist of alcoholics, nutritious alimentation, and tonic remedies. They will be noticed more fully in connection with diseases in the treatment of which they are oftener called for. (Vide Treatment of Pneumonitis, Chapter IV.)

A fatal result in acute pleuritis may be due to rapid and excessive effusion of liquid, as already stated. If the liquid accumulate sufficiently to endanger life, it should be at once withdrawn from the chest by aspiration. This measure is much more frequently indicated in chronic pleuritis, and will be considered in connection with the latter variety of the disease.

The measures which have reference to the promotion of absorption may continue to be indicated in the third stage; that is, for a certain period during the progress of absorption. When these measures have been carried to a sufficient extent, and the amount of liquid is considerably reduced, the patient is to be considered as convalescent. During convalescence the chief object is the re-establishment of the health of the patient. This is to be done by tonic remedies, a nutritious diet, and other hygienic means. Solid food, embracing a fair proportion of meat, may be allowed whenever taken with relish and digested. Alimentation is important; and if the appetite be small and the digestion weak, remedies to improve both are indicated. No apprehension need be felt that a diet as nutritious as can be taken without inconvenience will do any harm; on the contrary, the more nutritious the food which can be taken and digested, the more rapid the convalescence. Wine, spirit, or beer in small quantities, taken with meals, will expedite recovery. Going out of doors and gentle exercise are to be encouraged. The patient will gain more rapidly as regards appetite, digestion, and strength if not confined too long within doors, and with proper precautions no risk of harm is incurred.

The removal of the liquid which remains, the absorption of fibrin, and the development of new tissue leading to adhesion will go on rapidly in proportion to the rapidity with which improvement in the general condition takes place.

In the foregoing account of the treatment of simple acute pleuritis it is assumed that, exclusive of a small number of cases in which this disease destroys life either by asthenia or apnœa, its course is toward convalescence without becoming chronic. This is the rule, to which there are exceptions. If the disease become chronic, the measures of treatment indicated are those which will be considered in connection with chronic pleuritis.

The prevention of acute pleuritis hardly claims consideration. The abrupt and rapid development of the disease precludes the employment of prophylactic measures, and there are no premonitions which warrant our anticipation of its occurrence.

Marked dullness on percussion over the affected side, especially at the inferior portion, continues for some time after the effusion has disappeared, the symptoms, general and local, denoting recovery, and the vesicular murmur of respiration being heard over the whole of the affected side. This shows that fibrin remains to be absorbed, but it need occasion no apprehensions. After the effusion has disappeared, as shown by vesicular breathing and vocal resonance extending to the base of the chest, considerable dullness remains, and generally continues for several weeks.

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis: Anatomical Characters; Clinical History; Pathological Character; Causation; Prognosis; Diagnosis; Treatment; Thoracentesis.—**Empyema, Pyothorax, or Suppurative Pleuritis:** Diagnosis; Prognosis; Treatment.—**Pulsating Pleurisy.**—**Pleuritis with Pneumothorax, Pneumo-hydrothorax, Pneumo-pyothorax, or Pneumo-hæmorthorax:** Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—**Pneumothorax.**—**Circumscribed Pleuritis.**—**Hydrothorax.**

OF the varieties of pleuritis, the first to be considered is the simple or ordinary chronic form of the disease. Other varieties are suppurative pleuritis or empyema, and pleuritis with pneumothorax. Circumscribed pleuritis will claim some consideration. This chapter will be devoted to these affections, including a brief account of pneumothorax without pleuritis, and of hydrothorax.

Chronic Pleuritis.

ANATOMICAL CHARACTERS.—The anatomical characters in simple chronic or sero-fibrinous pleuritis are essentially the same as in the acute form. The pleural cavity contains serum and fibrin in variable relative proportions, but as a rule the quantity of fibrin is less and the accumulation of liquid greater than in acute pleuritis. Effusion frequently takes place to such an extent

that the affected side is more or less dilated. The lung is then compressed into a small solid mass, usually situated at the upper and posterior part; the thoracic walls are expanded in every direction; the intercostal spaces are pushed out to a level with the ribs or even beyond this level, and show no depression with the act of inspiration; the diaphragm may be depressed, pushing downward the abdominal organs situated in proximity to it—namely, the stomach, spleen, and liver; the lateral pressure may be sufficient to move the heart from its normal situation, and, if the effusion be in the left side, the heart may be carried quite into the space belonging to the right side of the chest.

The dilatation decreases as absorption of the liquid takes place, and contraction of the affected side succeeds. The latter arises from the fact that compressed lung does not readily resume its former volume when the pressure of the liquid is removed, in consequence of the layers of fibrin with which it is more or less invested, and sometimes because pleuritic adhesions have already taken place. Other things being equal, the extent of contraction is in proportion to the amount of the previous dilatation and its duration. Usually, the dimensions of the affected side in every direction are lessened, the shoulder is lowered, and lateral spinal curvature is likely to ensue. In some cases in which the lung expands to a certain point and becomes fixed by permanent adhesions at that point, the removal of the liquid below leads to a deep depression; the chest presents an appearance as if the lower ribs had been crushed inward. The contraction succeeding a large effusion is generally permanent. It becomes less marked after several months or years in some cases, and if the patient be young it may in the progress of time nearly disappear. In a patient who had chronic pleuritis with very large effusion at the age of seventeen years, followed by great contraction, I found, ten years afterward, the two sides presenting only a slight disparity. The formation of new connective tissue in the shape of fibrous thickening of the pleural membrane and of bands of adhesion between the pleural surfaces is more extensive after chronic pleuritis than after the acute form.

CLINICAL HISTORY.—Chronic pleuritis, in the great majority of cases, is a subacute affection from the first. Occasionally it follows the acute form of the disease. The chronic is a more frequent affection than the acute—a fact which shows that the latter does not usually precede the former, as has been stated by some authors. Of 35 recorded cases which I analyzed with reference to this point many years ago, the inflammation was subacute from the first in 29. The left side is affected oftener than the right, as in acute pleuritis. Of 42 cases, the left side was affected in 23. Of 78 cases analyzed by Blakiston, the left side was affected in 58.

This variety of pleuritis is often developed imperceptibly, and, as far as the symptoms are concerned, it may be one of the most insidious and latent of diseases. It is often overlooked by those who do not employ the physical methods of examination. Its development is not, as in the vast majority of cases of acute pleuritis, characterized by pain. Pain is often either wanting or so slight as scarcely to attract attention. In some cases, however, the pain is moderate or considerable, but falling much short of that intensity which belongs to the acute affection. Tenderness over the chest is slight or moderate, and may be wanting.

Cough and expectoration are frequently wanting, and are rarely prominent symptoms. The cough, if present, is dry, short, hacking, and the matter of expectoration consists of mucus, transparent or slightly opaque. If there be considerable expectoration and the matter expectorated be muco-purulent, either bronchitis coexists or the pleuritis is associated with phthisis.

The frequency of the respirations is increased, assuming the pleuritis to be accompanied by a large effusion of liquid. The increase, however, may be moderate while the patient is at rest, but it becomes marked on exercise. Deficiency of breath is also shown by inability to speak with a sustained expiration, the speech being interrupted at short intervals for a fresh inspiration. Dyspnoea is rarely present except on exercise. Here, as in acute pleuritis, the embarrassment of breathing depends much on the rapidity with which the effusion takes place. The suppression of the respiratory function of an entire lung in this affection, if it be slowly induced, does not usually occasion lividity of the face or prolabia.

The pulse is generally more or less accelerated, ranging from 80 to 120 per minute. It is small and compressible. There is, however, considerable variation in different cases as regards these characters of the pulse. The surface of the body frequently presents more or less capillary congestion. Sweating is apt to occur, especially during the night, and may be profuse without having been preceded by a chill or febrile movement. Irregular, slight chills, however, are not unusual, leading sometimes to the error of supposing the disease to be malarial.

The appetite is sometimes notably impaired, but sometimes it is preserved and the digestion continues good. Diarrhoea occurs in some cases. Generally, the countenance is pallid, denoting anæmia, but this is not true of all cases, and a healthy aspect is sometimes maintained. Emaciation is not usually marked, except when the disease is associated with phthisis. The strength is often retained in a remarkable degree. Patients usually do not take to the bed, and they may be able to be up and out of doors even with one side of the chest filled with liquid. I have known repeatedly persons in this condition to continue pursuits which required active muscular exertion.

This sketch of the symptomatology applies, of course, to cases of chronic pleuritis not associated with other affections furnishing symptoms which are combined with those belonging to the disease under consideration. It may be associated with phthisis. The coexistence of the latter affection renders cough more prominent, and gives rise to a more or less abundant expectoration. Emaciation and muscular feebleness are also more marked. Pericarditis coexists in a small proportion of cases. With this complication the circulation is more disturbed, there is more suffering from dyspnoea, and the symptoms in general denote greater gravity of disease. The affection may be developed in the course of either acute or chronic disease of the kidneys; under these circumstances general dropsy may be present, emaciation and feebleness are greater, and the tendency to asthenia is more apparent. In like manner, other affections which may be associated modify and add to the symptoms pertaining to the pleuritic inflammation.

The duration is variable, but the career rarely ends until after several weeks, and generally it extends over several months. As regards stages, when acute pleuritis has not preceded, cases do not come under observation until more or less effusion has taken place, and, it may be, not until the pleural sac is filled with liquid. It suffices to consider the career of the disease as consisting of two stages—one embracing the period during which the liquid either is accumulating or remains stationary, and the other embracing the period during which absorption of the liquid is going on. After absorption has made a certain amount of progress the patient may be regarded as convalescent.

PATHOLOGICAL CHARACTER.—Simple chronic sero-fibrinous pleuritis is a subacute inflammation, differing from the acute form of the disease only in a lesser degree of the inflammatory condition. The inflammation has no

special character, but is of a low grade of intensity, with a tendency to continuance for an indefinite period.

CAUSATION.—[The belief is universal that pleurisy may arise from exposure to cold and dampness, and is supported by the fact that it is most prevalent during the inclement seasons, the winter and spring. Large statistics compiled by von Ziemssen¹ show that the largest number of cases occur in January, the smallest in October. It is scarcely necessary to add that the causal relation between cold and pleurisy is indirect. This is proved by the fact that one individual exposed to cold may develop bronchitis; another, articular rheumatism; a third, nephritis; and a fourth, pleurisy. Cold, exposure, fatigue, and privation act merely by reducing the powers of resistance to the specific causes of disease, and it is in the same indirect manner that pleurisy is caused by blows and wounds.—H.] It occurs occasionally during the course of affections of the kidneys. In many cases it proceeds from internal causes which are not understood, and it is then said to be spontaneous. In a small proportion of cases the chronic follows the acute disease. In much the larger proportion the inflammation is subacute from the first.

An important point of inquiry relates to its pathological relations to phthisis. According to some authors, it is generally consecutive to and dependent upon a phthisical affection. There has been no evidence of this in a large majority of the cases which have come under my observation. Of 42 cases analyzed several years ago, the evidence of coexisting phthisis was present in only 3, and of a large number of cases which I have since observed I am sure that the two affections have been associated in but a small proportion. As, however, the occurrence of pleuritic effusion retards and contributes to the arrest of the progress of phthisis, the association of the two affections may sometimes exist without being apparent.

[It must be admitted also that, from our present bacteriological standpoint, the presence or absence of tuberculosis cannot be decided upon by a study of the physical signs alone. A pleural effusion cannot be declared non-tubercular until culture experiments and microscopic examination have yielded none but negative results so far as the bacillus tuberculosis is concerned. The fact that a patient recovers from a pleurisy does not necessarily indicate that it is non-tubercular, for tubercular processes in serous membranes, such as the peritoneum and pleura, are often remarkably benign.

An important practical contribution to this subject was recently made by Dr. Vincent Y. Bowditch of Boston, who investigated the results of the cases of pleurisy occurring in his father's practice from 1849 to 1879. He obtained satisfactory records of 90 cases, which, without entering into minute details, may be summed up in the concluding words of his paper: "The results of this investigation show us at least, first, that whether we can prove absolutely by such statistics that all pleurisies are tubercular or not, yet a large percentage of these patients who were afflicted with pleurisy, often in apparently chronic forms, recovered their health and have never had any recurrence of the original trouble nor development of subsequent pulmonary or otherwise tubercular trouble; second, that while undoubtedly there are many cases in which an attack of pleurisy is followed within a comparatively short space of time by pulmonary trouble—and therefore special care should be taken of the patient during convalescence from the former disease—yet we are not justified in giving such gloomy prognosis as we should be inclined by accepting the extreme views held by Landouzy and his followers."—H.]

Chronic as well as acute pleuritis occurs rarely in infancy. It is not of

¹ *Klinische Vorträge*, 1889.

infrequent occurrence in childhood and early life, but it is most frequent between puberty and middle life. It is of rare occurrence in the aged.

PROGNOSIS.—Simple chronic pleuritis, not associated with phthisis or complicated with any serious affection, and occurring in a healthy subject, tends to recovery. A fatal result may take place in consequence of a rapid and large accumulation of liquid, but instances of this are exceedingly rare. If death occur, it is generally from associated affections or complications.

Recovery takes place, leaving the affected side more or less contracted, and sometimes the contraction is so marked as, in connection with the lateral curvature of the spine which it occasions, to produce a considerable and permanent deformity. In general, however, the contraction which follows is attended with little or no inconvenience, and is not observed unless the chest be denuded and the two sides compared.

A permanent dislocation of the heart to the right side of the sternum is sometimes an effect of the removal of a large collection of liquid from the right pleural sac; and in some cases of pleuritis with large effusion in the left side the heart, which was dislocated by the lateral pressure of the liquid, is found on the right side of the sternum after recovery from the pleuritis, adhesions having taken place which prevent it from returning to the left side after the liquid is removed.

Phthisis becomes manifest sooner or later after recovery in a certain proportion of cases. In some of the cases in which this disease appears to be a sequel it may have existed prior to the pleuritis and have undergone arrest. The proportion of cases in which phthisis follows is not sufficiently large to show a predisposition to this disease derived from the pleuritis. The opinion, frequently and perhaps commonly entertained, that chronic pleuritis, when it does not supervene on a phthisical affection, predisposes strongly to the occurrence of the latter, I believe to be incorrect. This belief is based on my own experience. It is sustained by statistics communicated many years since by Blakiston.¹ Of 53 cases observed by that author, the patients remaining under observation for several years after recovery, not one became affected with pulmonary tuberculosis. This result is striking, for it might be expected that out of so large a number of cases of any disease, occurring, as does pleuritis, for the most part at an early age, a certain proportion would be likely in the course of several years to become phthisical. In estimating the influence of this or any disease in determining the subsequent development of phthisis, the liability to the latter, irrespective of antecedent affections, is of course to be taken into account.

The idea that chronic pleuritis affecting the right side of the chest denotes phthisis has been disproved by statistics reported by Bowditch.²

The mortality from chronic pleuritis, even without regard to associated affections and complications, is not great. The rate of mortality probably does not exceed that which several years ago I deduced from my recorded cases—namely, 17 per cent.

Recovery is understood to imply the removal, by absorption, of the effusion. The disease, however, may terminate in another way, leaving no local symptoms, the patient regaining good health. This consists in the affected side of the chest remaining permanently filled with liquid. The following case, illustrative of this termination, came under my observation in the Charity Hospital of New Orleans in 1861:

The patient, a man aged about forty-five, stated that he had been ill and confined to the bed for four days, having previously been in good health.

¹ *Practical Observations on Certain Diseases of the Chest, etc.*, Amer. ed., 1848.

² *American Journal of the Medical Sciences*, January, 1863.

In answer to inquiries suggested by the marks of cupping on the left side, he stated that he had had pleurisy several years before. The left side was dilated, everywhere flat on percussion, and the respiratory murmur suppressed. Death occurred on the third day after his admission, and my notes do not contain data showing the probable cause of death. The man presented a robust appearance, and declared that he was quite well when seized with illness four days before his admission. His habits were intemperate. On examination of the chest after death, the left pleural sac was found to be so resisting that it was removed entire and brought to the college. The sac was then opened with some difficulty, and a large amount of turbid liquid, estimated to be two gallons, removed. After the liquid had escaped, the pleural sac was sufficiently rigid to retain the shape which it had before being opened. A calcified fibrous tissue, from one-eighth to one-quarter of an inch in thickness, lined the entire pleura. The parietal portion of the membrane could in some places be stripped from this calcified tissue. Calcareous matter was abundantly deposited in the latter. The lung was compressed into a solid, small mass which resisted efforts at insufflation.

Another case, illustrative of a similar permanency of effusion, came under my observation in private practice. A lawyer, aged about thirty, had an attack of pleuritis, which confined him for some time to the bed, nine years before my first examination, in 1861. Five years afterward he was in excellent health, being entirely free from any pulmonary symptoms except deficiency of breath on exercise. Flatness on percussion existed over the whole of the left side, with suppression of respiratory sound and vocal resonance, except at the summit, where bronchial respiration and bronchophony existed. These signs were considered as denoting liquid in sufficient quantity to fill the pleural sac and compress the lung into a solid mass. The patient stated that he had been repeatedly examined since the attack of pleuritis nine years before, and there had been no change in the condition of the chest since his apparent recovery from that disease.

[Sudden death is a possible event in cases of pleurisy with large effusion, and may be due to torsion of the inferior vena cava at the point where it traverses the central tendon of the diaphragm. Bartels considers this a not uncommon accident. It is due to the traction exerted upon the vein by the displaced heart, and can scarcely occur except in cases of left-sided effusion.—H.]

DIAGNOSIS.—Owing to the latency of chronic pleuritis as regards the subjective symptoms in many cases, the existence of intrathoracic disease is often overlooked by those who do not employ physical exploration. Of the cases which have come under my observation, in not a few the patients have been supposed to have either dyspepsia, irregular malarial fever, hepatic trouble, or some ailment not connected with the chest. If the symptoms point to the existence of intrathoracic disease, patients are often supposed to be phthisical, and the cough, deficiency of breath, night perspirations, etc. rationally favor such a conclusion. A positive diagnosis can hardly be made without the aid of physical signs.

The signs on which, taken in connection with the history and symptoms, the diagnosis may be based are those denoting pleuritic effusion. The signs of effusion are the same in chronic as in acute pleuritis, and need not be again stated; but in chronic more frequently than in acute pleuritis the accumulation of liquid is so large as to occasion more or less dilatation of the affected side, and then are superadded signs obtained by inspection and palpation, notice of which was deferred in treating of the acute disease.

Dilatation of the affected side by liquid is apparent to the eye, and may

be ascertained by mensuration either with graduated tape or calipers. The intercostal spaces are pushed out to a level with the ribs, and may be bulging. The side is motionless or nearly so in the acts of respiration, the movements of the opposite side being exaggerated. By applying the fingers within the intercostal spaces, and making peripheral and diametrical percussion, a sense of fluctuation is sometimes obtained. The heart is moved from its normal situation, as ascertained either by palpation or auscultation. If the effusion be in the left side, the apex-beat and the maximum intensity of the heart-sounds are on the right side of the sternum, and they are carried toward the left lateral portion of the chest if the effusion be in the right side. [Another valuable sign of large left-sided effusion is a diminution or obliteration of the "semilunar space of Traube." On the left side, anteriorly and below, there exists, in health, an area of tympany having the shape of a half moon with its convexity upward. It corresponds to the splenic end of the stomach, and in cases of copious left-sided effusion is replaced in part or altogether by dulness on percussion. From the fact that Traube was the first to emphasize the diagnostic importance of this tympanitic region, it is known as the "semilunar space of Traube."—H.] The diaphragm is depressed, pushing downward the abdominal organs in contact with it. The addition of these signs renders the diagnosis of pleuritic effusion still more complete and positive than the signs which denote the presence of liquid without dilatation.

The presence of liquid is demonstrated by the introduction of a small exploring trocar, previously disinfected. A hypodermic syringe, the needle being sufficiently strong to obviate danger of its being broken off and remaining in the chest, answers for the exploratory puncture, or a small aspirating needle may be used. This should be resorted to in all cases, both of acute and of the different varieties of chronic pleuritis, in order to ascertain the character as well as the presence of liquid. With as well as without this exploration there is one liability to error in diagnosis—namely, carcinomatous or sarcomatous infiltration of an entire lung, which may cause an enlargement of its volume, and, a certain amount of pleuritic effusion coexisting, the signs may seem to denote simply chronic pleuritis. An exploratory puncture demonstrates the presence of liquid. The diagnosis can then be settled only by aspiration. Removing the liquid, the affected side remains enlarged; the needle or trocar even passes into a solid mass, as shown by its remaining fixed; that is, the point not movable while in the chest.

A sanguinolent effusion, if scorbutus be excluded, renders the coexistence of phthisis probable.

During the stage of absorption the signs show the progressive diminution of liquid until the quantity is no longer sufficient to occasion dilatation, and from this point the continued decrease in quantity is ascertained as in acute pleuritis. The contraction of the affected side which follows chronic pleuritis is more marked than that succeeding the acute affection.

TREATMENT.—The main objects of treatment in simple chronic pleuritis are twofold—namely, *first*, to effect the removal of the effused liquid; and *second*, to develop and sustain the powers of the system. For the first object the measures which may be employed are the same as in the second and the third stage of acute pleuritis, consisting of the milder hydragogues, diuretics, small blisters applied in succession over different portions of the affected side, and the use of iodine internally and externally. Bloodletting, general or local, is never indicated in chronic pleuritis.

In pursuing measures with reference to the first object, the second is not to be overlooked or neglected. Cases are often injudiciously treated in conse-

quence of the attention being too much engrossed with the measures to promote absorption; and these measures will do harm if continued too long or pushed too far. After a certain amount of effect has been produced, if these measures cease to be further effective, they should be discontinued, at least for a time; nor should they be persisted in if they fail to have any effect. Harm is produced by their injudicious employment in proportion as they debilitate.

The second object calls for tonic remedies, nutritious alimentation, the moderate use of alcoholic stimulants, and gentle exercise out of doors. These measures are always important, and they are pre-eminently so if from associated affections, complications, or the general condition of the patient the powers of the system be notably lowered. I have repeatedly seen a marked change for the better occur at once, followed by progressive improvement in all respects, on the discontinuance of measures having reference to the absorption of liquid, and the substitution of measures for building up the system. Hygienic measures—namely, nutritious diet and exercise in the open air under proper restrictions—are especially important.

A mode of effecting the first object—namely, the removal of the liquid—requires distinct consideration. Reference is now had to the operation of *paracentesis* or *thoracentesis*. The propriety of puncturing the chest when the accumulation of liquid is sufficient to place the patient in imminent danger is unquestionable. But it is a question whether it be not advisable to puncture although the patient be not in great distress or danger. It is clearly an object to get rid of the liquid, and the point is whether it be better to resort to the direct mode—that is, to puncture and withdraw it—or to endeavor to effect the object indirectly by purgatives, diuretics, etc.

Formerly, this operation was performed only as a *dernier ressort*, when little was to be expected from any measure. It was deferred as long as possible, sometimes on account of doubt as to the diagnosis, and because the perforation and introduction of air involves danger of an increase of the inflammation. A considerable opening was necessary in order to give free exit to the liquid, and it was difficult to prevent air from entering the pleural cavity. Objection to the operation on the score of diagnosis is now removed by our present knowledge of physical signs. Moreover, the operation was divested of all severity, and the liability to the introduction of air provided against, by the application of suction in 1850. The introduction of air, aside from the entrance of organisms giving rise to putrefactive changes, is objectionable, because its presence is an obstacle to the full expansion of the lung after the liquid is removed. Its introduction is prevented by the employment of a suction force in withdrawing the liquid. The operation is rendered trivial, because with suction a small exploring trocar suffices to make the puncture, which causes very little pain and closes as soon as the canula is removed.

The credit of the introduction of the practice of withdrawing the liquid through a small canula by means of suction—or, as it is now called, aspiration—is due to Bowditch. He operated in this way 250 times on 154 persons in the course of twenty years. In no instance was any permanent injury referable to the operation. It was in some cases repeated several times during the progress of the disease. In a considerable proportion of cases recovery appeared to be attributable to the operation. Immediate and great relief was obtained in cases which ultimately proved fatal. Bowditch has been led by his experience to operate in all cases in which the quantity of liquid induces either permanent or occasional dyspnoea of a severe character, and in all cases in which the pleural cavity is filled, if, after a reasonable amount of general treatment, the liquid do not diminish.

My own experience in the practice of the operation has been considerable, and I can testify in behalf of its innocuousness, the relief which it affords, and its value as a means of rescuing in some instances patients from a condition of imminent danger to life. The conclusions of Bowditch, as just stated, are not only sustained by his large experience, and at the present time by the experience of many others, but they are consonant with common sense. If, by an operation trivial with respect to pain or any evil effects, and easily performed, the effusion may be withdrawn at pleasure, this mode is certainly to be preferred to measures which are indirect, not very reliable, requiring considerable time, and producing more or less disturbance and debility of the system. An important advantage of the operation is, the liquid being removed before the lung has been subjected to long pressure and has become adherent by dense layers of fibrin or perhaps organized tissue, the expansion takes place more fully and is followed by less deformity of the chest from contraction of the affected side. It is a noteworthy fact that directly after the operation the temperature declines and may fall to the normal standard.

Thoracentesis by means of a small trocar with the aid of suction, the puncture made at a convenient point either behind, laterally, or in front, is admissible whenever the pleural cavity remains filled with liquid after a brief trial of the measures designed to promote absorption; and the operation should not be delayed whenever the accumulation of liquid is sufficient to involve danger or distressing dyspnoea.

For many years, in place of the suction-pump employed by Bowditch, I have used a simpler apparatus—namely, a small trocar and a canula fitted to screw upon the flexible suction-tube of Davidson's syringe. The canula should be provided with a stopcock. The trocar and canula being introduced into the chest, the trocar is withdrawn and the canula attached to the syringe; the liquid is then removed by means of the expansion of the India-rubber bulb after its compression with the hand. I have used this apparatus in many cases with satisfactory results. It has also been used with success by many others. After a certain quantity of liquid has been withdrawn, the patient often is seized with cough and experiences a distressing sense of constriction in the chest. These symptoms probably arise from the atmospheric pressure upon the thoracic wall and from the disruption of the pleural surfaces, united by fibrin, by the expansion of the compressed lung. They may also be in part due to the suction force exerted laterally upon the lung of the healthy side. They may be delayed, and sometimes avoided, by withdrawing the liquid very slowly, thus allowing time for the expansion of the compressed lung and the gradual accommodation of the parts to fill the vacuum occasioned by the removal of the liquid. When these symptoms occur the further removal of liquid should be postponed for another operation. As regards the quantity removed at one operation, much will be gained by following the injunction to withdraw the liquid slowly, especially when the patient begins to cough and complain of constriction. The advantage of my apparatus over the suction-pump is its greater simplicity, the ease with which it is managed, and a less liability to get out of order.

More recently an instrument for aspiration—or aspirator, as it is called—constructed on a different plan, was introduced by Dieulafoy. The peculiarity of Dieulafoy's aspirator consists in first producing a vacuum in a glass receiver, and then opening a communication between the latter and a canula or hollow needle introduced into the chest. The objections to the instrument are—first, being complicated, it is likely to get out of order; and second, it is expensive as compared with the suction-pump, and especially with that devised by me. A little appendage has been added to the canula to be attached to Davidson's syringe, so that it may be in an instant connected with the latter.

It is easy to secure more expansive force than is obtained by the ordinary syringe used for enemata, by having an instrument made especially for aspiration, with a larger and thicker India-rubber bulb.

A much simpler instrument than the aspirator of Dieulafoy, on the same principle, is a glass bottle from which, by an arrangement for that purpose, the air is withdrawn by means of a small syringe, and the communication with the canula within the chest then opened through a tube connecting the latter with the bottle. This kind of aspirator is as efficient as the more costly one of Dieulafoy.

Dieulafoy's aspirators are provided with small trocars and hollow needles. The latter should never be used in aspirating the chest. The sharp needle-points are liable to tear the lung with which it may come in contact after a certain quantity of liquid has been withdrawn, giving rise to pneumothorax.

[The first and most important step in thoracentesis is disinfection of the skin of the patient at the site of puncture, the hands of the operator, and the different parts of the aspirator. This is best accomplished by bathing them successively with a five per cent. solution of carbolic acid, a sublimate solution (1 : 1000), and finally with alcohol.—H.]

Failure in aspiration may be caused by the trocar carrying before it a portion of false membrane which prevents the liquid from being reached. With a view to obviate this difficulty, the trocar should be pushed with a certain degree of quickness and force into the chest. Another difficulty is the plugging of the end of the canula with floating pieces of fibrin. This obstruction may generally be removed by means of a probe.

Instances have been reported of grave symptoms, and even death, resulting from aspiration. They have been most frequently reported by French writers, who affixed to the condition the name *expectoration séro-albumineuse*, derived from one of the most prominent symptoms. The condition is characterized by dyspnœa, cough, with expectoration of frothy, watery, and sometimes blood-stained liquid, and the symptoms of collapse. A probable explanation is the hyperæmia which follows removal of pressure from the capillaries of the compressed lung, these capillaries being more or less impaired in their nutrition by long-continued pressure. Recovery is common, following the administration of heart-stimulants. I believe that the risk is almost *nil*, if the fluid be withdrawn slowly and aspiration be suspended as soon as cough or dyspnœa is produced. But even if this statement be not admitted, the risk is too small to constitute a serious objection to the measure if it be indicated. I may add that during the past twenty years aspiration has been practised almost weekly in the wards of Bellevue Hospital, and I have not heard of a single instance in which any serious consequences have resulted from it. Only one such instance has come within my cognizance in private practice. In this instance an alarming dyspnœa followed the removal of a large quantity of pus. This effect was temporary, and the case ended in recovery. It is probable that the effect in that instance was attributable to a too rapid withdrawal of the liquid. I had previously withdrawn a large quantity of pus in this case without any unpleasant symptoms.

[It is rarely advisable to remove more than fifty ounces of fluid at a single operation, but no stereotyped rule can be laid down with reference to this matter. I have removed more than one hundred ounces at one time with none but favorable results, while, on the other hand, I have been compelled to withdraw the canula, on account of violent cough, before thirty ounces had escaped.

It is impossible to withdraw all the fluid from the pleural sac, and fortu-

nately it is unnecessary, because its absorption often goes on with great rapidity when the pleural vessels are relieved of pressure.

After aspiration the attempts to promote absorption of the remaining fluid by means of counter-irritants, purgatives, diuretics, and diaphoretics should be renewed. It is true that these various measures may have been previously employed in vain, but experience proves that they may accomplish at one stage of the disease what they have failed to do at another.—H.]

Empyema—Pyothorax—Suppurative Pleuritis.

These names denote a form of pleuritis characterized by the accumulation of a purulent liquid in the pleural cavity. The term empyema expresses only the existence of pus without indicating its situation. Pyothorax is a better name, but this does not express the existence of pleuritic inflammation. Suppurative pleuritis is a simple title suggested as more fully expressive of the affection.

Suppurative pleuritis may be either acute or subacute at the beginning, but it becomes chronic. It is a more severe form of inflammation than sero-fibrinous pleuritis. At the beginning the inflammatory products may be the same in both diseases, but in suppurative pleuritis the emigration of white blood-corpuscles is greater, causing the fluid in the pleural cavity to acquire a purulent character. Sometimes the fluid is thick, creamy pus, but usually it is thin and sero-purulent or fibrino-purulent. There is less fibrin in the exudation than in sero-fibrinous pleuritis, suppurative inflammation checking the production of fibrin. The pleural membrane itself is more severely affected than in acute pleuritis. It is thickened and converted into a kind of granulation-tissue, containing leucocytes, new connective-tissue cells, and new blood-vessels. The inflammation may even extend to the subpleural tissues.

Suppurative pleuritis, at least in the great majority of cases, is not to be regarded as an intense variety of ordinary sero-fibrinous pleuritis, but as an inflammation depending upon some special cause. The micro-organisms which have been found in suppurative inflammations elsewhere have been observed in this affection. There are various micro-organisms capable of inducing suppuration, so that the specific infective agent is not the same in all cases. It is not probable that sero-fibrinous pleuritis can eventuate in suppurative pleuritis without the addition of some new special agent of infection. The inflammation has generally a suppurative character from the first, but in some cases the emigration of white blood-corpuscles is for some time insufficient to render the exudation distinctly purulent.

In rare instances the walls of the pleural cavity become gangrenous and the cavity contains a brownish, fetid fluid. The pleuritis is then designated as *gangrenous* or *putrid*. Putrid pleuritis is usually secondary to gangrene of the lungs, but it may occur as an independent affection. The putrefaction is the result of the invasion of the pleura with the bacteria of decomposition. In putrid pleuritis are found bacilli as well as micrococci.

Sometimes, as a result of empyema, but more frequently in connection with putrid pleuritis, the ribs become carious and the parietal pleura is easily detached from them.

There are no distinctive points pertaining to the symptomatology of suppurative pleuritis, and it is not necessary, therefore, to consider under a distinct head its clinical history.

As regards causation, suppurative pleuritis may be produced traumatically. It is sometimes secondary to lobar pneumonia. It may be developed in pyæmia or as a complication of other acute infectious diseases, and it may be

secondary to abscesses in adjoining parts, as in the lungs, the chest-walls, the liver, or the peritoneum. In many cases it occurs as an idiopathic or primary disease. As already stated, the special cause is probably, in most if not in all cases, infection with micro-organisms.

[In empyema consecutive to pneumonia the diplococcus of Fraenkel and the pneumococcus of Friedländer have both been found. In other cases the streptococcus pyogenes and the staphylococcus pyogenes, aureus, and citreus are present, and in putrid effusions the leptothrix pulmonalis.—H.]

DIAGNOSIS.—The signs as well as symptoms in suppurative pleuritis are not distinctive of this disease. They represent the presence of more or less liquid in the pleural cavity, and they are essentially the same when the liquid is purulent as when it is sero-fibrinous. The point of inquiry in regard to diagnosis is whether there be any means of determining that the liquid is purulent. This is an important point with reference to prognosis and treatment. The occurrence of chills, more fever, hectic paroxysms, etc. is not reliable in this differential diagnosis. As a rule, however, the axillary temperature is higher than in simple pleuritis. The symptoms and signs, in fact, exclusive of spontaneous perforation of the thoracic walls, will hardly warrant a positive diagnosis. But the purulent character of the liquid may be inferred with considerable confidence if the quantity progressively continue to increase notwithstanding the employment of measures to promote absorption. A serous effusion is generally either diminished or retarded by the use of hydragogues, diuretics, etc., but these measures are not likely to exert any influence upon a purulent liquid.

[Baccelli of Rome maintains that the whispered voice is audible over serous and inaudible over purulent effusions, and this statement, on account of the recognized authority of its author, has obtained general currency. "Baccelli's sign," however, is far from infallible, there being cases of empyema in which the whispered voice is plainly conducted, and cases of sero-fibrinous pleurisy in which it is inaudible.—H.]

A positive diagnosis, however, may be easily made by an exploratory puncture. A small trocar or the needle attached to a hypodermic syringe may be introduced into the chest and a little of the liquid withdrawn, when the gross and microscopical characters of the specimen thus obtained will at once settle the question. This procedure is warrantable as a means of diagnosis in view of the bearing on the prognosis and treatment. Indeed, the operation is so slight as to be in no wise objectionable. The needle should be sufficiently strong not to incur the risk of fracture, leaving a portion within the chest. I have known of several instances in which this accident has occurred.

Spontaneous perforation of the walls of the chest occurs, after a time, in cases of suppurative pleuritis. When this occurs, before ulceration of the integument ensues, a soft fluctuating tumor makes its appearance over or near the point of perforation. The appearance of such a tumor, developed rapidly without having been preceded by inflammation exterior to the thoracic walls, is at once significant of this variety of pleuritis. The size of the tumor may be observed to vary with forcible acts of inspiration and expiration. The action of the heart upon the liquid within the chest may communicate a pulsation to the tumor, and this may at first lead to a suspicion of aneurism; but an examination of the chest, by furnishing the evidence of the pleural sac being filled with liquid, will show the character of the affection. If the tumor be not opened, inflammation of the integument from distension and ulceration supervene, and the pus makes its escape from the tumor and the pleural cavity. "Paracentesis from necessity," as it is called, has then taken place. This result is almost exclusively due to suppurative pleuritis, but I

have known an instance in which spontaneous perforation took place when the liquid did not have the gross characters of pus.

In a smaller proportion of cases a spontaneous evacuation occurs in another direction. Perforation of the lung takes place, and the pus finds its way into the air-passages. The occurrence of this event is marked by a sudden and copious purulent expectoration. This expectoration continues for an indefinite period. With rare exceptions, air enters the pleural cavity, and the disease is converted into pneumo-pyothorax, which will presently be considered under a separate heading. Perforation successively of both the walls of the chest and of the lung sometimes occurs.

[There are numerous other paths by which a purulent effusion may make its exit. The diaphragm, for example, may be perforated and the pus be discharged into the stomach or intestine; or it may rupture into the peritoneum or burrow into the posterior mediastinum. In the latter event it may gravitate downward in the retro-peritoneal connective tissue, and finally reach the surface in the lumbar region, the buttock, or the thigh.—H.]

PROGNOSIS.—Suppurative inflammation of the pleura is a more serious disease than simple pleuritis, whether acute or chronic. Inasmuch as the pus cannot be removed by absorption, but must be evacuated either spontaneously or by puncture, the condition is analogous to that of a large abscess which, after opening, continues to discharge through a fistulous orifice. After the purulent contents of the pleural cavity are evacuated, the membrane continues to furnish pus, and thus the discharge continues indefinitely. Emaciation, debility, hectic paroxysms, etc. result from long-continued suppuration, and death takes place by slow asthenia. An unfavorable termination may be due, as in certain cases of simple pleuritis, to the coexistence of phthisis, pericarditis, or some other serious affection. In the case of a patient ten years of age which came under my observation sudden death followed perforation of the lung, the discharge of pus taking place rapidly and causing suffocation by filling the bronchial tubes.

Recovery from suppurative pleuritis, however, is by no means infrequent, and may reasonably be hoped for if the patient have a good constitution and the affection be uncomplicated. The prognosis is more favorable in children than in adults. The purulent discharge continues for weeks, months, and perhaps years, but progressively diminishes; pleuritic adhesions take place, the affection becoming more and more circumscribed, until at length they become universal, and the recovery is completed, leaving the affected side considerably or greatly contracted.

TREATMENT.—In the treatment of suppurative pleuritis no reliance is to be placed on measures to cause absorption of the purulent liquid. If the pleural cavity contain pus in considerable quantity, it will not be absorbed; but if life be sufficiently prolonged and thoracentesis be not resorted to, it will sooner or later make its way either into the air-passages or through the thoracic walls. Hydragogues, diuretics, blisters, etc. will not only prove unavailing, but they do harm by impairing the powers of the system. Thoracentesis should be performed as soon as the purulent character of the liquid is ascertained. Aspiration may be employed and repeated, but in many cases, owing to the reaccumulation of pus, this mode of performing thoracentesis will prove unsatisfactory. An opening should be made at the bottom of the pleural sac, allowing the pus to escape freely. Air will of course pass into the chest, and, since this is unavoidable, its ingress and egress should be unobstructed. A small orifice, not sufficient for the free escape of the pus and allowing air to be pent up within the pleural cavity, is injudicious. Hav-

ing made a free opening, allowing all the pus to escape, the orifice should be kept open by the introduction of an oakum tent. This is preferable to the insertion of a drainage-tube, which is a foreign body within the pleural cavity, and therefore objectionable. [Irrigation of the pleural sac is only permissible when the effusion is putrid, and should then be performed with the greatest care. Convulsions, paralysis, and fatal collapse have followed the washing out of the pleural cavity. Such accidents are sometimes due to the direct irritation of the heart and lungs; at others they are caused by emboli which are detached from the cavities of the heart or from the walls of the pulmonary blood-vessels by the impact of the injected fluid. Owing to their poisonous properties neither carbolic acid nor corrosive sublimate should be injected. Salicylic acid, boracic acid, and thymol are the best drugs for this purpose.—H.] I should add that I have known a complete withdrawal of the pus by a single aspiration to prove sufficient, but the probability of this result is small. Aspiration repeatedly performed has succeeded in several cases under my observation, but these cases are exceptional. There is no objection to giving aspiration a fair trial before resorting to a free opening. Indeed, this is generally advisable. In children, simple aspiration not infrequently effects a cure.

[A cure of empyema can only occur by obliteration of the pleural sac through adhesion of its opposed layers, and an indispensable requisite to such adhesion is contact between the costal and pulmonary pleuræ. Such contact must be the result of retraction of the thorax or expansion of the lung or of a combination of both these processes. In recent cases, in which the lung has been but a short time compressed, expansion predominates over retraction, and the cure is attended with little or no deformity. On the other hand, in old cases, in which the lung is carnified or bound down by adhesions, the contact of the pleural layers can only be the result of a sinking in of the chest-wall which may give rise to great deformity. The retraction of the thorax is greatly facilitated by resection of one or more ribs, and the amount of bone removed should depend upon the expansive power of the lung and the elasticity of the thorax. A correct decision with reference to this important matter can only be the result of experience.—H.]

If spontaneous perforation of the chest-wall take place, as denoted by the development of a fluctuating tumor, the latter may be at once opened; but if the perforation be at a point so far above the bottom of the sac that a portion only of the pus is evacuated, more or less remaining constantly below the point of perforation, a counter-opening may be requisite. Aspiration, however, may be fairly tried before resorting to this measure and before making an incision into the subcutaneous tumor.

If perforation of the lung take place aspiration should be employed, and if this do not succeed a free incision into the chest-wall should be made, provided the pus be not fully discharged by expectoration. The fact that only a portion of the pus within the pleural cavity is expelled through the pulmonary orifice is readily ascertained by means of the physical signs. In most instances perforation of the lung converts the disease into pneumo-pyothorax, but sometimes pus passes through the opening into the bronchial tubes without the entrance of air into the pleural space.

To support the powers of the system is an object of still greater importance in the treatment of suppurative than of simple chronic pleuritis. The importance is greater because there is more danger of death by asthenia, and in favorable cases the duration of the affection is longer. The measures to be employed for this object are the same in both forms of the disease.

[Pulsating Pleurisy.]

On page 51 it was mentioned that the tumor which forms in cases of "paracentesis of necessity" may pulsate synchronously with the heart's action. This remarkable occurrence demands a more extended notice. The term "pulsating empyema of necessity" was introduced by MacDonnell,¹ who was the first to publish a detailed account of cases of empyema characterized by one or more circumscribed pulsating tumors. It has since been ascertained that pulsation may occur without the pus having forced its way through the chest-wall so as to form a circumscribed tumor, and also that there may be pulsation when the effusion is serous. Pulsating pleurisy is therefore a more accurate term than pulsating empyema. In the great majority of cases, however, the effusion is purulent and occupies the left pleural sac.

Pulsating pleurisy is a rare disease. Alfred Keppler,² who, with reference to this point, examined the medical literature of more than two hundred years, found but 38 cases of the affection.

There are different opinions concerning the cause of the pulsation, and it is probable that it may be produced in different ways. Féréol believes that a certain amount of air in the pleural cavity is essential to its production, which air must be under considerable pressure, and therefore shut off from communication with the bronchi. Under such circumstances it acts as an elastic cushion, transmitting the cardiac pulsations through the effusion to the chest-wall.

Traube reports two cases of pulsating pleurisy in which pericardial effusion was also present. He believes the pulsation in his cases to have been due partly to the unusual mobility of the heart, which was suspended in the effusion and displaced to the right, and partly to the relaxation of the chest-wall caused by destruction of the costal pleura.

A careful study of the recorded cases makes it probable that the most important factors in the etiology of pulsating pleurisy are—(1) copious effusion; (2) paresis of the intercostal muscles, inducing relaxation of the thoracic wall; (3) a somewhat forcible heart-beat.

Air in the pleural sac under high tension and adhesion of compressed lung to the pericardium are co-operating, but not necessary, causes.—H.]

**Pleuritis with Pneumothorax—Pneumo-hydrothorax—
Pneumo-pyothorax—Pneumo-hæmothorax.**

The term pneumo-hydrothorax denotes the presence of air or gas and liquid in the pleural cavity. As the liquid, however, is either sero-fibrinous or purulent, hydrothorax, which signifies a purely serous liquid, is not strictly appropriate: the liquid is due to inflammation, and the affection is a variety of pleuritis. It would be more correct to say pleuritis with pneumothorax. Pneumothorax denotes the presence of air without liquid. The latter affection is rare, but it occurs and claims separate notice.

[Pneumothorax is apt to be overlooked at post-mortem examinations unless proper precautions are taken. As a rule, the gas in the pleural cavity escapes with more or less force when the knife penetrates the chest, but this can only occur when it is under positive pressure. The presence of pneumothorax is best demonstrated by thrusting into the pleural sac a hollow needle to which is attached a rubber tube the free end of which is immersed in water. If the pleura contains gas which is under positive pressure, bubbles will be seen

¹ *Dublin Journal of Medical Science*, March 1, 1844.

² *Deutsches Archiv für klin. Med.*, 1887, Bd. 41, p. 220.

rising in the water, and, if desired, the gas may be collected for analysis. If the gas in the pleura is under negative pressure, it may be made to escape by forcibly compressing the thorax.—H.]

ANATOMICAL CHARACTERS.—If the patient have survived sufficiently long after the perforation, the pleural cavity usually contains an inflammatory exudation. This exudation is in most cases purulent (pyo-pneumothorax), but is frequently sero-fibrinous (sero-pneumothorax). Sometimes the perforation is attended by hemorrhage into the pleural cavity (hæmato-pneumothorax). If the disease be associated with pulmonary gangrene, and exceptionally in other cases, the air and liquid are fetid in consequence of putrefaction.

The size of the perforation varies. It is usually small when the affection supervenes on phthisis, but in cases of gangrene it may be quite large. Usually, the site of the perforation can be demonstrated by inflating the lungs through the trachea. Sometimes, however, it is impossible to find the perforation.

The perforation may be found open or closed, or in the form of a valve-like structure which allows air to enter, but not to escape from, the pleural cavity. The tension of the enclosed air is usually greatest when the perforation is valvular. The perforation may be closed by a fibrinous layer. The lung on the affected side is compressed into a solid mass if this be not prevented by old adhesions.

CLINICAL HISTORY.—The occurrence of perforation of the lung is usually marked by acute pain denoting the development of pleuritis. The introduction of air and the speedy effusion of liquid give rise generally to notable dyspnœa, with accelerated breathing, accompanied frequently with lividity. The pulse is in most cases rapid and feeble. These symptoms show the supervention of a serious affection of some kind, and point to the chest as its seat.

In some cases the accelerated breathing and dyspnœa continue to be prominent symptoms, the patient suffering greatly, and perhaps being unable to lie down (orthopnœa), the affection ending fatally, usually under these circumstances after the lapse of a few days, and it may end fatally in the course of a few hours. But in other cases the violence of the symptoms subsides after a short time, and the dyspnœa may be moderate or wanting, save on exercise. In some instances even considerable exercise is practicable. As regards strength and the general condition there is much variation in different cases. In the majority of cases patients are confined to the room and bed, but sometimes they are able to be out of doors, preserving appetite and not presenting a notably morbid aspect. [The general condition will depend largely upon the nature of the disease of which the pneumothorax is a complication.—H.]

As an exception to the rule, pleuritis with pneumothorax from perforation is developed gradually and imperceptibly. It may remain for a greater or less period quite latent. In some instances the accumulation of liquid becomes large, the air disappears, and the affection is converted into simple pleuritis with effusion. In several instances of this kind which have fallen under my observation thoracentesis was resorted to, and the communication between the air-passages and pleural cavity through the perforation was resumed after the liquid was withdrawn.

CAUSATION.—It is estimated that from 80 to 90 per cent. of all cases of pneumothorax are due to the rupture of a phthisical cavity into the pleural

cavity. Although this rupture usually occurs in an advanced stage of phthisis, it may take place before any suspicion of this disease exists. The perforation is more frequently at the middle or inferior portion of the lung than at the summit. Gangrene, abscesses, and hemorrhages in the lungs are rare causes of pneumothorax. It is sometimes due to the bursting of an emphysematous bleb situated just beneath the pleura. As in such cases the air may not contain any inflammatory irritant, the pneumothorax may exist without any inflammatory exudation. Bronchiectasis may lead to rupture. Next in frequency to phthisis as a cause of pneumothorax is the ulceration of an empyema into the lung. When an empyema opens spontaneously through the thoracic walls, it may be that no pneumothorax follows, because the opening is sinuous and in some cases acts like a valve. Injuries of the chest which cause laceration of the lung are attended by pneumothorax. The most frequent of these is fracture of the ribs. Simple stab-wounds of the lung may occur without causing pneumothorax. A very small number of cases of pneumothorax are the result of communication between the pleural cavity on the one hand and the œsophagus, the stomach, or the intestine on the other hand. Ulcerative and cancerous diseases of these organs may lead to this abnormal communication.

It is held by some authorities that gas may be spontaneously generated in the pleural cavity by the decomposition of inflammatory exudations or of blood, [and it must be acknowledged that there are facts which strongly support this view. In the first place, there are numerous cases of pneumothorax in which the most careful search has failed to reveal any communication with the lung or other air-containing organ; and, secondly, it is now well established that there are micro-organisms whose activity is attended with the evolution of gas.¹—H.]

DIAGNOSIS.—When this affection is developed with marked symptoms in the course of phthisis, its existence should certainly be at once suspected; but the symptoms are not sufficiently distinctive of this affection, as contrasted with pleuritis and effusion without the presence of air, to warrant a positive differential diagnosis. Moreover, as just stated, the affection is sometimes latent, the symptoms not warranting even the diagnosis of pleuritis. A positive diagnosis, in short, must be based on physical signs, and these are easily obtained and very explicit.

[The results of percussion are by no means uniform, being dependent upon the tension of the air in the pleural sac. If the effusion is considerable, the dulness over the lower portion of the affected side is of course absolute. Over the air-containing portions of the chest there may be either tympanitic resonance or marked dulness. The resonance is tympanitic if the case is one of "open" pneumothorax—i. e. if there is a free communication between the bronchi and the pleural cavity, so as to render the atmospheric pressure equal on both sides of the thoracic wall.

On the other hand, when the air in the pleural sac is under great tension, as is the case when the perforation of the lung is of such a valvular character as to permit the entry of air into the pleura and prevent its exit, the percussion-note is dull. It is owing to this fact that pneumothorax frequently escapes detection, for the examiner, finding dulness on percussion, is apt to be misled into the belief that it is caused by pulmonary consolidation or pleuritic effusion.

The belief seems to be almost universally prevalent that air in the pleural sac must give rise to tympanitic resonance under all circumstances, and there-

¹ See *Bulletin of the Johns Hopkins Hospital*, July-August, 1892, for an account of the *bacillus aerogenes capsulatus*, by Prof. W. H. Welch, M. D.

fore the fact is here emphasized that the percussion-note over an air-containing cavity may be dull.

Another diagnostic mark of pneumo-hydrothorax is that the fluid is freely movable in the pleural sac, and therefore the line corresponding to its level may be made to vary in accordance with the position of the patient. For example, when the patient is made to lie on the sound side the lateral region of the diseased side, which has been previously dull, may become tympanitic. Again, when the decubitus is dorsal the line of dulness is higher behind than in front, whereas when the patient assumes a sitting posture this line becomes horizontal.

The auscultatory signs of pneumo-hydrothorax depend largely upon the existence or not of communication with the bronchi. If the aperture of communication is open, the respiration is amphoric or even distinctly metallic, whereas if it is closed all respiratory sound may be suppressed.—H.]

Respiratory sound is sometimes wanting over the whole of the affected side. Over the compressed lung bronchial respiration may often be found. The ordinary cavernous respiration is sometimes heard, but in most cases amphoric respiration and amphoric voice or echo are present, either limited or diffused over the whole of the affected side, and metallic tinkling is generally conjoined. The presence of these striking and distinctive signs renders the diagnosis easy and positive, taken in connection with other signs.

Succession almost invariably develops a splashing sound, frequently having the same kind of musical intonation as the respiration, voice, and tinkling sounds. This proof of the presence of air and liquid is positive, and it enables the diagnosis to be made in an instant.

[A pathognomonic sign known as the coin-sound (*bruit d'airain*) may be obtained by auscultatory percussion. The auscultator applies his ear to the back of the chest while an assistant holds one coin against the anterior portion of the affected side and strikes it with another. There is then conveyed to the ear of the examiner a ringing metallic sound which is absolutely diagnostic of air in the pleural sac.—H.]

The affected side is frequently dilated, and presents the same appearances as in cases of dilatation from liquid either in simple or suppurative pleuritis.

Leyden has called attention to the rare occurrence of abscesses containing air, situated just below the diaphragm, either on the right or the left side, oftener on the right, between the diaphragm and the upper surface of the liver.¹ The diagnostic features of these abscesses were first recognized by Barlow and Wilks in 1845. Leyden calls the affection pneumothorax subphrenicus. Cossy calls it false pneumothorax. The abscesses result from perforating ulcers of the stomach or duodenum from which gas is derived, circumscribed peritonitis having been produced. The signs of pyo-pneumothorax are present. Leyden diagnosed the affection in two cases, each connected with perforating ulcer of the stomach. The differential points are—the presence of the respiratory murmur from the clavicle down to the third rib; the extension of the respiratory murmur downward by deep inspiration; and, at first, absence of cough and expectoration. The abscesses may burst eventually into the lungs. A capital point in the diagnosis is the history of the development of the abscess with the signs of peritonitis following symptoms referable to the stomach or intestine.

[The signs of diaphragmatic hernia and pneumo-hydrothorax are almost absolutely identical. In both the heart is displaced and the lung compressed, and in both the signs derived from percussion and auscultation are alike. Metallic tinkling may also be obtained in both. The chief point of distinc-

¹ *Zeitschrift für klinische Medicin*, Bd. 1, p. 320.

tion is that diaphragmatic hernia is either the result of a severe injury or is congenital. In the latter instance the signs may suddenly disappear on account of the return of the bowel to its normal position, and reappear with equal suddenness. The peculiar rumbling sounds ("borborygmi") caused by the movement of air in the displaced bowel are pathognomonic of hernia. The appearance of the signs of pneumo-hydrothorax immediately after a severe injury should always excite suspicions of diaphragmatic hernia.—H.]

PROGNOSIS.—The prognosis in cases of pleuritis with pneumothorax is always unfavorable. In this statement traumatic cases are excluded; the prognosis in these cases is generally favorable. Of the cases of empyema in which pneumo-pyothorax is produced by perforation of lung there is a fair prospect of recovery if other circumstances be favorable. If the affection be connected with pulmonary gangrene, death takes place generally within a short period. Other things being equal, when it occurs in the course of phthisis a fatal termination is speedy in proportion to the progress which the latter affection has made. There is a wide variation in different cases as regards its duration before a fatal ending; in many cases it ends fatally within a few days or weeks, but sometimes life is prolonged for months or even years. It may continue for an indefinite period, the patient experiencing so little inconvenience as to consider himself in fair health. The following unique case will serve to verify this statement, and also to illustrate the latency of the affection occurring in connection with phthisis:

I received from Dr. J. H. H. Burge of Brooklyn, N. Y., the left lung which he had removed at a post-mortem examination made two or three days before. The patient, aged eighteen, an accountant, was seized four days before his death with an acute affection which proved to be pneumonitis affecting the lower lobe of the right lung. At the time of the attack he considered himself in fair health. He was attended by Dr. Burge, who found the physical signs denoting pneumonitis, and the affected lobe was found after death in the second stage of this disease. On an examination of the chest, in addition to the pneumonitis Dr. Burge discovered the signs of pneumo-hydrothorax affecting the left side. Metallic tinkling and amphoric respiration and voice were well marked. The upper portion of the chest on this side yielded a tympanitic, and the lower portion a dull, resonance on percussion.

On inquiry as to the previous health the patient declared that he was well when attacked with the acute disease; that is, four days before his death. On close questioning, however, it was ascertained that he had had a slight cough for a year, but so slight that he thought nothing of it. He was not conscious of any deficiency of breath, was not subject to pain in the side, and, in short, there were no symptoms pointing to so grave an affection as pleuritis with pneumothorax.

The left lung was completely condensed from compression. The lower lobe was readily inflated; the upper lobe but slightly, owing to the free escape of air through a perforation as large as a crow's quill situated on the anterior aspect of this lobe about midway from the upper to the lower extremity. On closing the aperture this lobe was readily inflated. The perforation was gaping, the orifice being surrounded by a cartilaginous rim. On passing a probe into the aperture it entered a small cavity of about the size of an American walnut. The cavity was smooth and lined by a membrane. This was the only cavity in the left lung, and there were no phthisical deposits. The whole surface of the lung was covered with fibrin, which was dense and closely adherent. The pleural cavity contained more than a quart of turbid liquid which was not fetid. When this side of the chest was opened air escaped with force, emitting no fœtor. The upper portion of the right lung

contained several phthisical cavities, the largest of the size of an English walnut, with small phthisical deposits.

TREATMENT.—The treatment of pleuritis with pneumothorax in most cases embraces only palliative and sustaining measures. The severity of the pain and the distressing dyspnœa frequently call urgently for measures to procure relief. Opium, soothing applications to the chest, and the ethereal preparations are indicated for this object. The powers of the system are to be sustained by tonic remedies, alcoholic stimulants, and a nutritious diet. These measures will generally serve only to mitigate the sufferings of the patient and prolong life; and in the rare cases in which the affection continues for months, years, or indefinitely, and is not incompatible with comfortable health, there is no special treatment to be pursued, the main object being to invigorate and support the powers of the system.

If the patient suffer greatly from dyspnœa arising from dilatation of the affected side, the chest may be punctured as a palliative measure. I have resorted to this operation to the great relief of the patient. The air will be likely to reaccumulate and the side become again dilated as before; but I have known this not to occur for some weeks, and the operation may be repeated as often as called for by the dyspnœa arising from the dilatation.

[If an exploratory puncture has shown the effusion to be serous, it is better to postpone operation unless the pressure-symptoms are severe. The reason for postponing operation in the absence of urgent symptoms is that the withdrawal of the fluid is apt to be followed by the escape of fresh quantities of air into the pleural sac; or, if the pulmonary fistula has closed, the removal of the fluid may cause it to reopen. On the other hand, by placing the patient in the most favorable hygienic environment and postponing operation there is a fair chance for both air and fluid to be absorbed.]

In order to diminish the danger resulting from suddenly-reduced pressure, Potain has constructed an apparatus with which sterilized air may be pumped into the pleural cavity immediately after the performance of paracentesis.

In most cases the fluid is purulent, and in that event the treatment is the same as that of empyema—namely, free incision and drainage.

If the patient is in an advanced stage of pulmonary phthisis the question of operation is a difficult one, and can only be decided by a careful study of the individual case. If the pressure-symptoms are severe and life seems to be imperilled, incision and drainage without resection of ribs should be performed. The improvement following this procedure is often decided, while, on the other hand, it sometimes appears to stimulate the tubercular process to renewed activity.—H.]

Pneumothorax.

The term pneumothorax denotes the presence of air, without liquid, in the pleural cavity. Under these circumstances pleuritis either does not exist or it is not accompanied by effusion. This affection is certainly extremely rare. Its occurrence has been doubted, but its existence is sufficiently established. In cases of pneumothorax without pleuritis the perforation of lung is not incident to either gangrene or phthisis, but is probably connected generally, if not invariably, with emphysema, which may not be general but circumscribed. Emphysematous dilatation of the air-cells, perhaps confined to a few lobules at the margin of a lobe or an emphysematous bleb, may lead to a minute rupture through which air is forced by the acts of breathing into the cavity of the pleura. Under these circumstances rupture may be caused by lifting a heavy burden, severe coughing, or violent exertions of any kind.

The perforation, as remarked by Gairdner, may be no larger than a pinhole. The presence of the air does not excite pleuritis, but the accumulation may be sufficient to compress the lung into a solid mass, as in pleuritis with large effusion, dilating the affected side and removing the heart from its normal situation.

Pneumothorax without effusion from pleuritis is characterized by the absence of the symptoms and signs denoting inflammation and the presence of liquid. The patient suffers chiefly from the mechanical effects of the presence of air. These effects relate exclusively to the respiration and circulation. There is little or no febrile movement; the appetite, digestion, and nutrition are not affected, and the vital powers are maintained. If the affection were to end fatally, it would be by apnoea, assuming that pleuritis is not developed sooner or later. It is unquestionable that this affection may end in recovery. Under the influence of compression the perforation may become sealed up by a circumscribed pleuritis with the exudation of fibrin, or by the adhesion of the pleural surfaces at the point of perforation, the lung again expanding and resuming its function. Gairdner has quoted the report of a remarkable case illustrative of the occurrence of pneumothorax without pleuritis, and of its favorable course and termination.¹ Gairdner regards this case as unique in respect of the distinctness of the clinical facts on which the diagnosis was based. A case equally striking, and not less distinct as regards the diagnosis, has fallen under my observation. The important points taken from the history of this case, which was recorded very fully, are as follows:

A Polish peddler, aged twenty-nine, was admitted into hospital January 29, 1856. He stated that twelve days before his admission, being apparently in perfect health, he was attacked suddenly with a sharp pain in the region of the left nipple, accompanied with shortness of breath. This occurred while he was carrying his pack, which weighed about seventy pounds. He had no cough or expectoration. The pain soon disappeared, but the want of breath obliged him to give up his occupation and led him to the hospital. He was a vigorous man, weighing about one hundred and seventy-five pounds. He presented a healthy aspect, complaining only of deficiency of breath on exercise. This difficulty did not prevent him from being up and walking freely about the ward.

The left side was dilated and the intercostal depressions obliterated; the resonance over this side was purely tympanic, and auscultation furnished a well-marked amphoric echo without any respiratory sound. Subsequently amphoric respiration became extremely well marked, together with metallic tinkling. The heart-sounds showed the heart to be to the right of the sternum.

After a month there was considerable improvement with regard to the deficiency of breath on exercise. The dilatation of the left side was no longer apparent, and the intercostal depressions became visible; vesicular respiration extended from the summit to the nipple, and the amphoric sounds, with the metallic tinkling, had disappeared.

Three weeks afterward the patient felt sufficiently improved to leave the hospital and return to his occupation. The respiratory murmur on the left side was feeble, but everywhere appreciable, with no abnormal modification save in intensity, and no amphoric sounds. The impulse of the heart was felt on the left side of the sternum.

The patient consulted me a month after his discharge from the hospital. He had returned to his occupation of peddling, carrying his pack on his back as before. He had experienced no difficulty from want of breath until three

¹ *Clinical Medicine*, Edinburgh, 1862, p. 381.

days before his visit to me, but for three days the deficiency of breath on exercise had been considerable. On examination of the chest the left side was everywhere tympanitic; there was no respiratory murmur on that side, and the heart was on the right side of the sternum. No amphoric sounds. He complained of nothing but the want of breath; excepting this he was well.

I did not see the patient afterward for eleven months. At the end of that time he called to see me with another patient. After his former call upon me he gave up peddling and became a farm-laborer. He now appeared and reported himself to be perfectly well. The respiratory murmur was everywhere heard over the left side, but was slightly weaker than on the right side. The apex-beat of the heart was in its normal situation. The left side laterally and posteriorly presented to the eye slight contraction.

This was a case of simple pneumothorax without pleuritis. A pinhole perforation at a weak point or the rupture of an emphysematous bleb probably took place in consequence of the muscular exertion of carrying his pack. He had nearly recovered when, on resuming his occupation, the perforation was reopened and the pneumothorax reproduced. Recovery again took place, and after the lapse of several months appeared to be permanent.

A sufficient number of cases of pneumothorax without pleuritis to serve as a basis for the clinical history and prognosis are not yet available. The infrequency of the affection is such that the collection of a considerable number of cases for analysis cannot soon be expected. The case just given, and the case reported by Gairdner, go to show that a favorable prognosis may be entertained. The physical signs are those of pneumo-pyothorax or pneumo-hydrothorax, excluding those denoting the presence of liquid. The affection is to be differentiated from diaphragmatic hernia.

As regards treatment, it is obvious that no special course of medication is called for. The compression of lung probably favors the healing up of the perforation, so that it would not be advisable to puncture the chest in order to allow the air to escape. Active exercise or muscular efforts, as in straining, are to be avoided, not only during the continuance of the affection, but for some time after recovery, lest the orifice may be reopened, as in the case just detailed. Soothing embrocations to the chest will be useful as palliatives, but nothing can be gained by active counter-irritation. A nutritious diet may be allowed. Cathartics, diuretics, and rubefacients are not indicated.

Circumscribed Pleuritis.

The frequency with which pleuritic adhesions over a limited area are found after death is proof that circumscribed pleuritis often occurs. But the inflammation which results in these adhesions is often subacute, and generally occurs without giving rise to much pain or other disturbance. As already stated, circumscribed pleuritis is secondary to some pulmonary affection, especially phthisis and pneumonitis. It differs from a primary general pleuritis in not giving rise to pleuritic effusion. Fibrinous exudation is sometimes small, and perhaps may be altogether absent, the adhesions taking place purely by a hyperplasia or proliferation of the connective tissue. Limited to the pleura investing the diaphragm (diaphragmatic or phrenic pleuritis), inflammation is supposed to give rise to symptoms which are distinctive—namely, hiccough attended with pain, and pain referable to the diaphragm in the acts of coughing. It may be doubted, however, if these symptoms be sufficient to mark the situation of inflammation or to distinguish inflammation from pleurodynia. If from the symptoms circumscribed pleuritis be suspected,

the treatment indicated embraces moderate counter-irritation, soothing applications to the chest, and anodyne remedies. The successive attacks of circumscribed pleuritis which occur during the progress of phthisis, and which lead to firm adhesions, are seldom accompanied by much pain and only call for palliative measures.

Circumscribed collections of sero-fibrinous or purulent liquid are usually, if not always, preceded by general pleuritis, which has led to the adhesions surrounding the space in which the liquid is contained. These collections may be situated at the lower part of the chest, between the lung and diaphragm or between the lobes. The previous history and the appearances of the chest will generally show the prior existence of general pleuritis. The diagnosis of circumscribed collections of liquid is not always easy. For the physical signs the reader is referred to works which treat more fully of thoracic diseases. The treatment embraces the measures for promoting absorption, and if the liquid be purulent, this fact having been demonstrated by means of the exploring trocar, it is advisable to effect its removal by a free opening after a trial of repeated aspirations. The latter have been successful in some cases under my observation.

Hydrothorax.

Hydrothorax, using the term correctly, is not a variety of pleuritis, but it is noticed in this connection because, as far as certain symptoms and physical signs are concerned, it has points in common with pleuritis accompanied by liquid effusion. In the proper sense of the term it denotes a dropsical affection. The effused liquid is serum devoid of fibrin. The effusion is not a result of inflammation or any other affection of the pleural membrane, but proceeds from those conditions relating to the blood and circulation on which dropsical effusion in other situations depends. [The chief constituent both of inflammatory effusions and dropsical transudations is albumin, but the amount of this substance is much greater in the former than in the latter. The determination of the percentage of albumin in a fluid withdrawn from the pleural cavity may therefore be of diagnostic importance, but it requires an analysis too elaborate for clinical purposes. The specific gravity of the fluid furnishes all the information that is practically required by the clinician. In inflammatory effusions this has been observed to vary between 1015 and 1023, whereas in mere transudation it is generally below the former figure. As a general rule, if the specific gravity of the fluid is above 1018, it may be set down with certainty as inflammatory.—H.] Hydrothorax very rarely, if ever, occurs alone, but is an element of general dropsy; that is, dropsical effusion exists at the same time in the peritoneal cavity and in the subcutaneous areolar tissue, the latter constituting either œdema or anasarca. As a rule, in cases of general dropsy the hydrothorax is subsequent to the anasarca and to hydroperitoneum.

The signs which denote the presence of liquid in the pleural cavity are applicable alike to inflammatory and dropsical effusion. The proof afforded by the change of level of the liquid, corresponding with changes of the position of the body, is more constantly available in hydrothorax, because fibrin is not present to agglutinate the pleural surfaces and lead to permanent adhesions. But the distinctive feature of this affection is the existence of effusion in both pleural cavities. Hydrothorax is bilateral, provided the pleural cavity on one side be not abolished by universal adhesions due to a previous attack of pleuritis, whereas pleuritis when it is primary is unilateral. The amount of dropsical effusion, however, in both sides is generally not uniform. It is not uncommon to find in the pleural cavity on one side a quantity of liquid

considerably larger than is contained in the cavity on the other side. It may then be laid down as a rule that if the physical signs show the presence of liquid in both sides and general dropsy coexist, the affection is hydrothorax. A friction murmur is of course not developed in this affection.

Symptoms denoting inflammation—namely, pain, cough, and febrile movement—do not belong to the clinical history of hydrothorax. The respirations are increased in frequency, and the patient suffers from deficiency of breath or dyspnœa in proportion to the amount of dropsical effusion. Existing in both sides, it is obvious that the embarrassment of respiration will be the same as if all the liquid were in one pleural cavity, and twice as much as if the effusion in one side were unaccompanied by an equal effusion in the other side. If there be considerable effusion dyspnœa will be marked, amounting perhaps to orthopnœa, and death by apnœa may be due to the amount of effusion. Cardiac lesions producing obstruction of the mitral orifice especially favor the occurrence of hydrothorax after these lesions have led to dilatation of the right cavities of the heart.

The measures of treatment in hydrothorax are those indicated in general dropsy, and these need not be considered in this connection. Aspiration should be resorted to as a palliative measure if the amount of effusion be sufficiently large to occasion much suffering, although not sufficient to endanger life. If there be any danger from apnœa, aspiration is to be employed without delay. It is an unobjectionable measure. I have resorted to it frequently. As there is no obstacle to the expansion of the compressed lung in cases of hydrothorax, all the effused liquid may be at once removed without the distress which is liable to accompany aspiration in cases of pleurisy.

It should be added that, in some cases in which it is dependent on mitral obstruction, hydrothorax is greatly out of proportion to the amount of dropsical effusion in other situations. I have repeatedly observed prompt, complete, and permanent relief procured by the hydragogue operation of elaterium in these cases, but, as a more prompt and less debilitating measure, aspiration is to be preferred.

CHAPTER IV.

PNEUMONITIS.

Seat of the Inflammation.—Varieties: Acute Lobar Pneumonitis; Anatomical Characters; *Laws of the Disease*; Clinical History; Causation; Diagnosis; Pathological Character; Prognosis.

HAVING considered in the preceding chapters inflammation affecting the serous membrane investing the lungs, inflammation seated in the pulmonary substance or parenchyma is next to be considered. The latter is called *pneumonitis* or *pneumonia*. Pneumonia is the name commonly used, but *pneumonitis* is the more appropriate term, being in conformity with the plan of distinguishing inflammatory affections by the suffix *itis*. The latter term will be adopted in the headings, but elsewhere the two names will be used indifferently. The question at once arises, What constitutes the parenchyma or substance of the lungs? These terms relate to the pulmonary lobules, which are composed of air-cells, infundibula, alveolar passages, and bronchioles. A bronchus after it enters a lobule is called a lobular bronchus or bronchiole; it divides dichotomously once or twice, and terminates in the

alveolar passages, into which open the air-cells, air-vesicles, or alveoli. The alveolar passages also divide a few times, and end in funnel-shaped spaces called infundibula, the walls of which are composed of thickly-placed air-vesicles. The lobular bronchi are devoid of cartilage-plates and of mucous glands, and are lined with a layer of low cylindrical ciliated epithelial cells. The walls of the air-cells and alveolar passages are composed of a homogeneous basement-substance containing a few oval nuclei of connective-tissue cells and a rich network of elastic fibres and of pulmonary capillaries. They are lined with a single layer of flat polygonal cells, some of which are small, nucleated, and granular, others larger, non-nucleated, and homogeneous in appearance. It is only the nucleated, granular, epithelial cells which take any active part in inflammatory diseases of the lungs. In acute pneumonitis the inflammation is seated in the air-cells and bronchioles. The differences in structure between the membrane composing the wall of these parts and the bronchial mucous membrane, together with a difference of function and of blood-supply, will serve to account for the fact that the inflammation in pneumonitis may be limited to the pulmonary substance, and also the fact that in bronchitis the inflammation rarely extends to the pulmonary parenchyma. This is in accordance with a pathological law—namely, that inflammation of a structure does not, as a rule, extend to another structure, however proximate, which has important anatomical differences or which differs as regards its functions. Some striking examples of conservatism in disease will be found to hinge upon this pathological law. The fact also that the lining membrane of the air-cells is not, strictly speaking, a mucous membrane will account for important differences pertaining to the inflammatory products of pneumonitis when compared with bronchitis and other mucous inflammations. The relation of the air-cells to the terminal branches of the pulmonary artery is also involved in the pathological phenomena of inflammation of the parenchyma of the lungs.

The different forms of pneumonitis may be classified as fibrinous or lobar, catarrhal or lobular, purulent, fibrous, and caseous or tubercular. Caseous pneumonitis and fibrous pneumonitis will be considered in connection with phthisis.

Acute Lobar Pneumonitis—Pneumonic Fever.

Acute lobar pneumonitis is the disease called by German writers *croupous pneumonia*. By others, especially French writers, it is sometimes called *fibrinous pneumonitis*. According to the view which will be presented in treating of the pathological character of the disease, each of these names is incorrect, and they all imply that the disease is a purely local inflammation, whereas there are sufficient grounds for regarding it as an essential fever. A more appropriate name, therefore, is pneumonic fever. The name acute lobar pneumonitis is here retained in conformity with usage and for the sake of convenience for reference.

ANATOMICAL CHARACTERS.—The first appreciable change resulting from acute inflammation is the same here as in other situations—namely, active congestion accompanied by transudation of serum. This is known as the first stage or stage of congestion or engorgement (*engouement*). The inflamed portion of the lung is heavier than in its healthy state; on section the cut surfaces present a dark-red appearance, and a bloody, frothy liquid flows in abundance. The affected portion of the lung presents the same appearance as in œdema with marked congestion. The microscopical examination shows the pulmonary capillaries widely distended with blood, and the

air-cells filled with a serous fluid containing red blood-corpuscles in abundance, a few white blood-corpuscles, and larger granular cells which are the epithelial cells washed off by the watery transudation from the blood. In this stage the affected portion of the lung does not sink in water.

In the second stage, usually called the stage of red hepatization, the air-cells and bronchioles become filled with a solid exudation and cease to contain air. The solidified lung is of a brownish-red color, non-crepitant, and presents an appearance not unlike that of the liver, whence the name hepatization. Upon its cut or torn surface it presents a very characteristic granular appearance, due to the projection of the little solid masses which distend the air-cells and bronchioles. In a lung previously affected with emphysema these granules are very large and distinct. When examined soon after death the cut surface is dry; later, a viscid, turbid, reddish fluid may be made to escape. The substance of the lung breaks down under the pressure of the finger more readily than in its healthy state; that is, it is more friable. Its volume is about equal to that of the lung in a state of full inspiration, and it does not collapse when the chest is opened. Its weight is much increased; a single lobe solidified by inflammatory exudation increases in weight from one to two pounds, and an entire lung solidified may acquire an additional weight of four pounds. Owing to the absence of air, portions of the solidified lung sink when thrown into water. Examined with the microscope, the substance filling the air-cells and small bronchi is found to be composed of a network of fibrillated fibrin containing in its meshes a large number of pus-cells or white blood-corpuscles and of red blood-corpuscles. A few desquamated and proliferating epithelial cells of the alveoli and a variable amount of amorphous granular matter are also present. The reddish color of the lung in this stage is due to congestion and to the large number of red blood-corpuscles present in the exudation. Some of the air-cells often appear to be completely filled with fibrin and red blood-corpuscles, conveying the impression of an extravasation of blood. Probably most of the red blood-corpuscles escape by diapedesis. There can be little doubt that the pus-cells are emigrated white blood-corpuscles. The lung-texture is not essentially altered by the inflammatory process. It contains, especially in the interlobular connective tissue, some emigrant cells.

When the brownish-red color of the solidified lung gives place to a gray color, the lung is said to be in the stage of gray hepatization. The granular appearance is then less distinct and the surface is moist. The red blood-corpuscles are fewer in number, but the leucocytes are more abundant and contain molecules of fat. The lung may present the appearance of gray hepatization after death within a few days from the onset of the disease, or the aspect may be that of red hepatization after the disease has lasted two weeks or more. Most frequently the lung is found in the condition of mottled hepatization; that is, of mixed gray and red. It is usually considered that gray hepatization is a later stage of red hepatization, the inflammatory products being in process of absorption. Absorption may take place with great rapidity. The statement by Rindfleisch and others that the greater part of the exudation is expectorated is certainly incorrect. The matter expectorated, in general, bears no proportion to the quantity of exudation, and there are cases in which the exudation disappears without any expectoration.

In the third stage, or stage of absorption,¹ the red blood-corpuscles lose their coloring matter, the leucocytes undergo fatty degeneration, the fibrin

¹ Anatomically, it is customary to reckon four stages of pneumonitis—viz. engorgement, red hepatization, gray hepatization, and resolution. As red hepatization and gray hepatization cannot be distinguished from each other clinically, they are here combined into one stage, that of consolidation.

becomes granular, and an effusion of serum takes place, so that a kind of granulo-fatty emulsion is formed suitable for absorption by the lymphatics and blood-vessels. In favorable cases after the removal of the exudation the air-cells are found to have sustained no damage. The pulmonary structure remains intact while the exudation remains, and its functional capacity is fully restored after the exudation disappears.

When after death the color of the inflamed lung is yellow or grayish-yellow, the granular appearance absent, the tissue soft and exuding a creamy fluid, the lung is said to be in the condition of "purulent infiltration." [This term, introduced by Laennec, is in most cases a misnomer, for, although there is an active immigration of leucocytes into the alveoli, the process of fatty degeneration of the alveolar contents undoubtedly predominates, and gives the exudate its creamy, purulent appearance.—H.] The exudation which fills the air-cells consists almost wholly of pus, and pus-cells are present abundantly in the interlobular tissue, but the lung-tissue is not broken down. This condition of so-called purulent infiltration is thought to favor the formation of pulmonary abscesses in which collections of pus take place in cavities resulting from breaking down of the lung-tissue. Gangrene of the affected portion of lungs sometimes occurs, but this, as well as the occurrence of abscess, is extremely rare. Lobar pneumonitis never terminates directly in caseous degeneration, as has been claimed by some writers. When phthisis supervenes upon lobar pneumonitis an infection with the tuberculous virus must have occurred.

It is probable that in rare instances lobar pneumonitis terminates in interstitial pneumonitis characterized by a new growth of connective tissue in the walls of the air-cells. Little nodules of connective tissue may grow from the alveolar walls into the interior of the air-cells, which are thereby more or less completely occluded. There is, however, a difference of opinion as to whether these cases of interstitial pneumonitis apparently following lobar pneumonitis are not from the beginning a peculiar form of pneumonia not to be identified with the ordinary lobar variety. The symptoms, however, at the onset of the disease may not be distinguishable from those of lobar pneumonia.

Pleuritis with fibrinous exudation is developed in the portion of the pleura covering the affected lobe or lobes of the lung. This concurrent pleuritis is never absent except in those rare cases in which the pneumonitis has not extended to the surface of the lung. The pleuritis is circumscribed and dry; much liquid effusion occurs only as an exception to the rule. To these exceptional cases with liquid effusion may be applied the term *pleuro-pneumonia*, although in a strict sense nearly every case of pneumonia is *pleuro-pneumonia*.

More or less bronchitis, affecting the bronchial tubes within the affected lobe or lobes, usually exists with pneumonitis. In some cases, however, the pneumonitis passes through its whole course without affording any evidence of this circumscribed bronchitis. Bronchitis affecting the bronchial tubes of both lungs is sometimes, but rarely, present with pneumonitis. When these two affections are combined it is accidental; bronchitis, as the primary affection, does not tend to the development of pneumonitis, and the latter has no tendency to give rise to bronchitis save within the affected lobe or lobes.

[The heart is generally flabby and pale, but the muscular fibres of the organ are found with the microscope to be in a healthy state. Occasionally they present the signs of fatty degeneration, apparently of recent origin. The liver is usually hyperæmic and enlarged, while the spleen, as in other infectious diseases, is enlarged, softened, and congested. The kidneys are also congested, and often present the appearances of parenchymatous inflam-

mation. The mucous membrane of the intestine is frequently in a catarrhal condition, and its glandular apparatus (solitary follicles and Peyer's patches) are abnormally distinct.—H.]

To the foregoing sketch of the anatomical characters may be added certain laws of the disease, which are best presented in this connection. One of these relates to the situation of the pulmonary affection. Pneumonitis attacks, in the great majority of cases, the lower lobe, and the lower lobe of the right oftener than of the left lung. Exceptionally, it sometimes attacks primarily an upper lobe, and in these cases, as a rule, the disease is more severe; but to this rule there are exceptions. The disease very rarely, if ever, attacks two lobes simultaneously, but it invades not infrequently in succession a second and even a third lobe. The inflammation does not extend from one lobe to another, but whenever a new lobe is affected it is the seat of a new invasion. The lobes of one lung may be successively invaded or a single lobe on both sides; or, an entire lung being first affected, a lobe of the other lung may be attacked. In the two latter cases the pneumonitis is said to be double. The name "crossed pneumonia" has been applied to the disease when the lower lobe of one lung and the upper lobe of the opposite lung are affected.

The inflammation extends at least over an entire lobe, as the name lobar pneumonitis implies, in the great majority of cases. There are exceptions to this rule. I have known some instances in which the physical signs clearly showed the occurrence of inflammation extending over a limited area, without any evidence of the circumscribed pneumonitis being a complication of any other pulmonary disease. In a lobe invaded secondarily—that is, one lobe being already affected—the inflammation is sometimes found after death to have extended over a portion only of the lobe. This fact I have repeatedly noted, but perhaps had the life of the patients been prolonged the whole of the lobe would have been affected.

The whole of the lobe first invaded is not at once affected. The inflammation begins at a certain point or at several distinct points, and extends from lobule to lobule until the entire lobe is involved. The point or points of departure may be at either the upper or lower extremity of the lobe, and at either the superficies or centre of the lobe. The diffusion of the inflammation over the lobe takes place with more or less rapidity; sometimes a few hours suffice, but in some cases it occupies several days. The progress of the solidification from the exudation may be determined very accurately from day to day or from hour to hour by means of physical signs.

The inflammation very rarely ends with the occurrence of engorgement only, without exudation. Solidification almost always occurs, and, when the inflammation is not secondary to another pulmonary disease, usually extends over the lobe or lobes invaded.

With respect to the situation and extent of the affection, the following are the results of an analysis of 121 cases:¹ In 29 cases it was limited to the lower lobe of the *right*, and in 25 cases to the lower lobe of the *left* lung. It extended over the whole of the *right* lung in 27, and over the whole of the *left* lung in 9 cases. It was limited to the upper lobe of the *right* lung in 8, and to the upper lobe of the *left* lung in 3 cases. It was seated in the lower lobe of both lungs in 8 cases.

CLINICAL HISTORY.—The division of acute pneumonitis into stages is based upon differences as regards the anatomical characters at different periods of the disease. The *first* stage embraces the period during which the affected lobe is

¹ "Clinical Report on Pneumonia, based on an Analysis of 133 Cases," by the author. Vide *American Journal of the Medical Sciences*, January, 1861.

in the state of active congestion or engorgement. This stage is called the stage of engorgement. The disease is considered as passing into the *second* stage when the affected lobe or a greater part of it has become solidified by the inflammatory exudation. This stage is called the stage of solidification or hepatization. In the *third* stage the affected lobe is in one of two conditions. If the disease pursue a favorable course, the third stage begins when it is evident that absorption of the exuded matter is going on, and convalescence takes place during this period. This may be called the stage of resolution. If the disease pursue an unfavorable course, the third stage is called the stage of purulent infiltration.¹

The duration of each of these stages varies much in different cases. The stage of engorgement may last for only a few hours. I have known an entire lobe to be solidified by two pounds of exudation matter, as determined after death, in less than twelve hours. Not infrequently this stage does not extend beyond twenty-four hours. But sometimes the solidification occupies two, three, or four days, and in some cases even a longer period. In the majority of cases this stage is from twenty-four to forty-eight hours in duration. The stage of solidification may also be of short duration. I have known resolution to begin and to make considerable progress in twenty hours. But this may not be evident for two, three, or four days, or even for a considerably longer period. In the majority of cases the duration of this stage is from two to four days. The stage of resolution is still more variable. There is a notable difference in different cases as regards the rapidity or slowness with which the solidifying deposit is removed. It is very rarely the case that the resolution is completed in less than three or four days, and generally eight or ten days are required. In some cases two or three weeks elapse before the air-cells are restored to their normal condition, and occasionally the resolving process is even much more protracted.

In the great majority of cases acute pneumonitis begins with a well-pronounced chill, frequently accompanied by rigors. The thermometer in the axilla shows an increase of temperature, although coldness exists as a subjective symptom. The invasion is usually abrupt, with few or no premonitions. The attack is liable to occur during the night. Coincident with or speedily following the chill is the occurrence of pain. Sometimes, however, pain is not felt until several hours after the chill. The pain is frequently severe. It is acute, lancinating, and in all respects identical with the pain in acute pleuritis. It proceeds from the pleuritis developed in conjunction with the pneumonitis. As a rule, the intensity of the pain is in proportion to the amount of coexisting pleuritis; but it is true alike of pleuritis thus developed as a complication and when it occurs primarily that it is sometimes attended with little or no pain. Cases of pneumonitis differ considerably as regards this symptom, and it may be quite prominent or present in a moderate degree or altogether wanting. The pain is usually referred to a circumscribed space at or near the nipple of the affected side. This limitation of the pain is a point distinctive of pneumonitis as compared with pleuritis.

Cough is usually present at or soon after the invasion. It is more or less prominent. It is sometimes wanting. It is painful in proportion as pain is a prominent symptom irrespective of the cough. The cough is frequently accompanied by expectoration. The matter at first expectorated is scanty,

¹ [This term, which is retained in conformity with usage and for the sake of convenience, has already been commented upon. The lung may present the appearance of suppuration without there being any *infiltration* in the proper sense of the word. It is probable that the process which, when observed post-mortem, is called purulent infiltration occurs in every case of pneumonia, and is an indispensable prerequisite to the absorption of the exudate.—H.]

transparent, and viscid, and in a certain proportion of cases it soon assumes characters which are highly distinctive of the disease. It becomes semi-transparent, adhesive, and has a reddish tint like that of iron rust; hence it is commonly known as the rusty expectoration. This appearance is due to a small quantity of blood which has become intimately mixed with the matter in its passage from the smaller to the larger bronchial tubes. The adhesiveness is such that when a considerable quantity has accumulated it adheres so closely to the bottom of the vessel as to remain when the vessel is inverted. The rusty expectoration is by no means uniformly present. The matter is in some cases semi-transparent and adhesive without the reddish tint. It may have a yellowish tint, as if mixed with a little bile, which, however, is not the fact. It sometimes contains blood in abundance, and when the blood is of a dark color it is what is called the prune-juice expectoration. It is to be borne in mind that expectoration in some cases of pneumonitis is entirely wanting.

Pyrexia exists at the outset, together with pain in the head, loss of appetite, thirst, prostration, heat of skin, etc. The pulse varies much in frequency in different cases, ranging from 80 to 120, and is more or less full and hard. The thermometer in the axilla indicates more or less increase of heat, the increase in mild cases not exceeding 104° F. An increase above this point always denotes severity of the disease. A sudden increase of temperature points to the invasion of a new lobe or to some intercurrent affection. Cases differ greatly as regards general or constitutional disturbance, the system being much more tolerant of the disease in some persons than in others.

The respirations are increased in frequency. This may depend on the pleuritic pain if it be marked, and also on the interruption of the function of hæmotosis in the portion of lung affected.

These are the important symptoms belonging to the clinical history of the beginning and during the first stage of the disease. During the stage of solidification the symptoms change. Pain, if it have existed, diminishes or ceases. Cough and expectoration continue, but the cough is less hard and painful and the expectoration is effected with more facility. The matter expectorated loses its rusty appearance, and becomes opaque, less adhesive, and more abundant. It is now the expectoration of resolving bronchitis. It is furnished chiefly by the bronchial tubes within the affected portion of lung, and is abundant in proportion as the bronchial mucous membrane is involved in the inflammation. [On careful examination of the sputum it is seen to contain opaque particles which, when separated and unravelled by shaking in water, may be demonstrated to be composed of fibrinous casts of the terminal bronchi. The microscope is not necessary for their recognition, their true nature becoming apparent when they are dissected out upon a glass slide and held before a dark background. These casts are almost pathognomonic of acute lobar pneumonitis, the only other affection in which they are observed being fibrinous bronchitis. Microscopically they are seen to be composed of parallel bundles of fibrin in the meshes of which are imbedded blood-corpuscles, both white and red, and fat-granules. Ciliated epithelial cells may also be adherent to them.—H.] The pyrexia continues, but with diminished intensity. The pulse in this stage may be small and deficient in strength, especially if more than one lobe be involved, owing to the obstruction to the pulmonary circulation, which diminishes the quantity of blood received from the lungs by the left auricle, and owing also to the amount of material withdrawn from the blood and deposited in the air-cells. The respirations are increased in frequency out of proportion to the increased frequency of the heart's action, in consequence of the solidified portion of lung taking no part in the respiratory function.

These are the modifications of the symptoms, assuming a single lobe only to be affected and that the course of the disease is favorable. The invasion of another lobe is rarely accompanied by a chill. The pyrexia persists or is increased, and the respirations become more frequent, accompanied perhaps by labored breathing, marked dilatation of the *alæ nasi*, and dyspnœa. The affection, however, of an entire lung does not always give rise to symptoms denoting great gravity of disease. The pyrexia is not always intense, and may be slight; the respirations may be but little increased in frequency; cough and expectoration may be not only not prominent, but wanting, and the system may be but little disturbed.

[The type of pneumonic fever is continuous, there being, in uncomplicated cases, no intermission, and little remission until the *crisis* arrives. Up to this time the difference between the morning and evening temperatures is seldom more than 2.5° F. It is true that, occasionally, between the third and fifth days there is a fall of temperature so decided as to give rise to the belief that the crisis has arrived. This idea, however, is soon dispelled by the temperature returning in a few hours to its former level and there remaining for several days longer. The crisis or critical defervescence may occur at any time between the third and fourteenth days, but in the greater number of cases is on the seventh. The fall of temperature at this time is so rapid and so great that the diagnosis of pneumonia may be made with great certainty by mere inspection of the temperature-chart. The temperature generally begins to decline in the evening or during the night, and defervescence may be so rapid that by the following morning the body-heat is normal or subnormal. A drop of from six to seven degrees in the course of twelve hours is by no means rare. Exceptionally, in favorable cases, the fever may be prolonged until the tenth, twelfth, or fourteenth day. The defervescence under such circumstances takes place gradually by *lysis*—a mode of termination which is usually due to some complication.

The crisis is occasionally preceded by symptoms of an alarming character, such as chills, convulsions, and delirium. These are in reality a part of the crisis itself, and were in fact described by the older writers under the title *perturbatio critica*.

With the decline of temperature the pulse diminishes in frequency, the skin becomes moist, sometimes bathed in perspiration, and the patient falls into a sound sleep, from which he awakens much refreshed and with a sensation of being delivered from an intolerable burden. The urine now voided throws down a copious sediment of urates, which circumstance caused the older writers to believe in a critical elimination of the *materies morbi*.—H.]

If, however, the disease pass into the stage of suppuration, the symptoms denote an unfavorable course. The pulse becomes more and more frequent and feeble. The expectoration is abundant and purulent. The respirations are frequent. The strength of the patient fails, and death takes place by *asthenia*, the accumulation of morbid products in the air-tubes frequently contributing to the fatal termination.

There are certain symptoms belonging to the clinical history of pneumonitis which are not included in the foregoing sketch of its symptomatology. One of these relates to the urine. While the process of exudation is going on, and after solidification has taken place, until resolution begins the chlorides frequently are greatly diminished or disappear from the urine. The disappearance of the chlorides from the urine is not peculiar to pneumonitis. It is observed in other diseases. It is not, therefore, a diagnostic character of the disease, but it constitutes evidence either that the exudation is going on or that resolution has not begun. It is stated that the chlorides are found in abundance in the matter expectorated during the time of their disappearance

from the urine. The quantity of urine is in general more or less diminished. The urea eliminated exceeds the amount in health, and, owing to the diminished quantity of water, the urates are often deposited in abundance when the urine becomes cold. The increase of urea denotes an abnormal destructive metabolism of nitrogenous substances. It is not uncommon for the urine to contain a trace or a moderate quantity of albumen. The presence of albumen is probably due to systemic venous congestion or to an altered condition of the blood, as in other acute general diseases. Albumen in abundance in the urine denotes coexisting renal disease.

Delirium not infrequently occurs in acute pneumonitis. It may be mild and merely incidental to the pyrexia; but it is sometimes a prominent symptom. It may be active, the patient attempting to get out of bed, resisting efforts of restraint, and perhaps using violence; or it may be of the low, incoherent, muttering kind, such as occurs in typhoid fever. Delirium is more likely to occur if the upper lobe be affected than if the affection be limited to the lower lobe. It is evidence of gravity of the disease in proportion as it is prominent, active, and persisting. It is likely to occur in spirit-drinkers.

A dusky redness of one or both cheeks, the margins of the redness being abruptly defined, is frequently observed, and, if the hectic flush of pulmonary tuberculosis be excluded, is quite distinctive of acute pneumonitis. When confined to one cheek it does not follow, as was formerly supposed, that the pulmonary inflammation is seated on the same side. It is not uncommon for an herpetic eruption to occur upon the face, more especially around the mouth. [Herpes labialis occurs too frequently in the course of pneumonia to be regarded as a mere coincidence, and not often enough to justify the classification of the disease among the eruptive fevers. In some epidemics it is observed in a large percentage of cases, while in others it is rare. Statistics of Finkler show that there is a larger percentage of recoveries in the cases attended with herpes.—H.]

Slight jaundice is an occasional concomitant, due to duodenitis. It occurs especially in spirit-drinkers. Its occurrence is probably accidental. At all events, it is not associated often enough to show any pathological connection between pneumonitis and hepatic disease. Owing to the accumulation of blood in the right cavities of the heart, and the consequent congestion of the systemic veins, the liver sometimes becomes more or less enlarged.

The occurrence of abscess and gangrene is accompanied by symptomatic phenomena denoting these events. The collection of pus in an abscess leads to a sudden and copious purulent expectoration if the life of the patient be sufficiently prolonged, and the existence of a cavity may be determinable by physical signs. This is a grave event, but it by no means necessarily renders the disease fatal. It occurred in 4 out of 133 cases which I recorded and analyzed, and 2 of these 4 cases ended in recovery. I have notes of a case, in addition to the 4 cases just referred to, in which a series of purulent collections were expectorated and the recovery was complete. The infrequency of gangrene is shown by its having occurred in but 1 of 133 cases. The disease proved fatal in that case. Since the analysis of these cases I have known gangrene to occur to a limited extent in a case which ended in recovery. Its occurrence is shown by the characteristic fetor attending expectoration, together with the appearance of decomposed pulmonary tissue in the matter expectorated.

The combination of other affections with acute pneumonitis will of course involve the addition of symptoms derived therefrom. In malarial districts it may be conjoined with periodical fever. This is an important complication as regards danger and therapeutical indications. The existence of the pneumonitis may serve to interrupt to a greater or less extent the regular

succession of periodical paroxysms, and the latter may tend to obscure the phenomena of the pulmonary affection. Pneumonitis occurring in the intemperate is liable to lead to the development of delirium tremens. The complication is always serious, and is important with reference to treatment. It occurred in 8 of 133 cases. Pericarditis is another grave complication. This occurred in 8 of 133 cases.

The supervention of certain symptoms is expressed by the term *typhoid pneumonitis*. This term denotes the existence of symptoms analogous to those which belong to typhoid fever, of which the most prominent is low, muttering delirium. A distinction is here to be made between typhoid pneumonitis and typhoid fever with pneumonitis as a complication. Pneumonitis is liable to be developed in the course of typhoid fever, the latter being the primary affection; but in the so-called typhoid pneumonitis the latter is the disease, certain of the typhoid phenomena being superadded. In other words, the typhoid state may be developed in connection with pneumonitis as with other affections, but this typhoid state does not involve the essential fever designated as typhoid. [Typhoid fever may also begin with the signs and symptoms of pneumonia, constituting the so-called "pneumo-typhus" of German writers. Cases of this sort are doubtless sometimes included under the head of typhoid pneumonia.—H.] There is not sufficient ground for considering "alcoholic pneumonia" as a distinct variety, but habits of spirit-drinking occasion certain distinctive features—namely, jaundice and the phenomena of delirium tremens; the ability to resist and recover from the disease is also thereby impaired.

The duration of acute pneumonitis, when uncomplicated, varies within pretty wide limits. Dating from the attack to the time when the patient could be pronounced convalescent in 30 cases, the shortest was five and the longest twenty-three days. The mean duration was a fraction over twelve days. In 14 fatal cases the shortest duration from the attack to the time of death was three, and the longest twenty days, the mean duration being a fraction over ten days.

CAUSATION.—Statistics show that no period of life involves either exemption from, or a notable proclivity to, this disease. It occurs under five years of age, but not often. Cases are less infrequent between the ages of five and ten. Of 118 cases, the patients all were over ten years of age; 13 were under twenty; 44 between twenty and thirty years; 37 were between thirty and forty years; 17 were between forty and fifty years; 7 were between fifty and sixty years; and in no case was the age over sixty. Cases, however, are not infrequent after the age last named. [According to E. F. Wells,¹ the mortality from pneumonia is lowest between the ages of five and twenty. "From twenty to forty years the proportion is increased somewhat, to be again considerably augmented during the next score of years. Old age comes on with a large—the largest—and increasing prevalence."—H.] The disease occurs much oftener among males than females. The analysis of my cases with reference to occupation does not show that any particular calling predisposes to this disease, but the proportion of laborers engaged in outdoor work over those employed within doors shows that they are most liable to the disease who are exposed to the vicissitudes of the weather. Not infrequently the attack is excited by some unusual exposure, such as working in the cold and wet or sleeping out of doors at night. The large proportion of hospital cases in which patients are addicted to excessive drinking shows that causative influences proceed from intemperance. In 10 of 37 cases in which the habits were noted the attack followed a debauch. It is questionable whether the

¹ *Journal of the American Medical Association*, March 30, 1889.

abuse of alcohol acts directly as a cause; probably the disease is caused by circumstances incidental to intemperance, such as exposure to cold, etc., these acting as exciting causes.

The association of periodical fever and pneumonitis has already been adverted to. My observations do not show the existence of any pathological connection between these affections. There is no ground for the conclusion that persons subject to intermittent fever are thereby more prone to pneumonitis, or that the latter affection tends to reproduce an attack of the former. Their coexistence is due to the coincidence of the causes proper to each.

With respect to causative influences pertaining to other pulmonary affections, facts show that bronchitis does not eventuate in pneumonitis. The same is true of pleuritis. Tuberculous patients are not particularly prone to the disease, and when it does supervene it may or may not affect the upper lobe, in which the deposit of tubercle is most abundant. Certain pulmonary affections—namely, emphysema, asthma, and chronic pleuritis—are so infrequently associated with pneumonitis as to show that, instead of involving a predisposition to this disease, they afford more or less protection against it. Pneumonitis is not often developed in persons affected with organic disease of the heart.

Pneumonitis occurs as a complication of other than pulmonary diseases. It is not infrequently developed in the course of typhus and typhoid fever, *rubeola*, dysentery, etc. The different affections of the kidneys have been supposed to stand in a causative relation to it. My own experience does not furnish evidence of such a relation. In not one of 133 cases analyzed was the disease preceded by albuminuria.

It occurs in certain seasons of the year in preference to other seasons. It occurs everywhere much oftener during the winter than during the summer months, and in our Northern States cases are more frequent in the spring months than at any other season. In this country the disease occurs in the Middle and Southern much oftener than in the Northern States. It prevails much more in some years than in others. In sections of the Southern States it prevails at times sufficiently to be considered as endemic. It is the prevalent disease during the winter months in these States, and, affecting especially the negro population, often proves the scourge of the sugar and cotton plantations of the South. It is a severer disease in the Southern sections of the country than at the North, being more liable to extend beyond a single lobe and proving fatal in a larger proportion of cases. This liability is greater in the same district in some years than in others. In some years also there is an unusual tendency in the disease to attack primarily an upper lobe. Such a tendency is manifest at the time of writing these remarks. Within two months (October and November) in hospital practice I have met with five cases in which the disease has been limited to an upper lobe, being about one-half the cases which occurred under my observation during this period.

In a large proportion of the cases of acute pneumonitis the disease is apparently developed spontaneously; that is, it is not referable to any obvious causative agency. When it appears to follow exposure to cold, it is probable that this acts only as an exciting cause co-operating with the action of a special cause. Litten has described cases of acute lobar pneumonitis following two or three days after contusion of the chest without any external wound. It is possible that in these cases physical changes in the lung produced by the contusion favored the development of a special infectious agent of pneumonia. Direct injury of the lung, as in stab-wounds and gunshot wounds, has no tendency to cause lobar pneumonia.

Clinical evidence seems inadequate to prove contagiousness. Instances in

which persons in the same neighborhood and members of the same household are attacked successively may be explained by supposing an exposure in common to an extrinsic cause. Yet if it be demonstrated that the disease can be produced in an inferior animal by inoculation, this fact is proof of communicability, and its apparent incongruity with clinical experience is to be accounted for, as in the instance of pulmonary phthisis, by supposing a peculiar predisposition, or, in other words, a favorable soil, to be an essential factor in the causation.

[Pneumonia is now universally recognized as an infectious disease, and for the following reasons:

(1) Like most infectious diseases, it runs a definite, self-limited course.

(2) The relation between the inflammatory process in the lung and the constitutional symptoms is far from uniform. The fever and other symptoms and signs of infection may, and often do, precede the local affection, and it is the rule for the fever to vanish before there has been any demonstrable diminution in the area of pulmonary inflammation. Again, the constitutional symptoms may be of severest type when the amount of lung involved is small; while, on the other hand, the course of the disease may be benign when an entire lobe or lung is consolidated. Facts like the above cannot be explained satisfactorily on the theory that the general symptoms are secondary to and dependent upon a mere local inflammation.

(3) Another proof of the infectious nature of pneumonia is that it often prevails in epidemic form. Examples of its epidemic prevalence in prisons, barracks, and asylums are too numerous to mention. One of the most remarkable epidemics occurred in Middlesborough, England, in 1888. Out of a population of about 70,000 there were 369 deaths from pneumonia, 288 of which were males.¹ There are accounts of village epidemics in which the track of the disease was very similar to that of the most contagious affections; that is, it would show a decided preference for certain streets and neighboring houses. For example, in an epidemic which prevailed in Tübingen in 1881, "thirty cases happened in houses which had in previous years contained patients with pneumonia."²

Although obliged by such facts as those above mentioned to regard pneumonia as an infectious disease, it must be confessed that its precise etiology is one of the most difficult questions in pathology. The diplococcus of Fraenkel is the organism most commonly present in the inflamed lung. It was found in 10 consecutive cases by Dr. Welch of Johns Hopkins Hospital, and in a much greater number (46) by Dr. Guido Banti of Florence, Italy.³ In one of Banti's cases staphylococci were also present, and in 4 of Welch's cases pus organisms were also found.

In 1886, Weichselbaum examined 129 cases of pneumonia with reference to the organisms in the inflamed tissues. He found Fraenkel's diplococcus in 94 cases (80 primary, 14 secondary); Friedländer's bacillus in 9 (8 primary), while the remainder were associated with the streptococcus pyogenes in 21 (13 primary), and the staphylococcus pyogenes aureus or albus in 5 (all secondary).

From such observations as those just referred to it appears evident that cases which do not depart either clinically or anatomically from the type of pneumonia may be associated with different species of infective organisms.

¹ There is a decided discrepancy in the reports of this epidemic, E. Klein (*Centralblatt für Bakteriologie und Parasitenkunde*, May 3, 1889) giving the population as about 40,000 and the deaths as about 240, while Sturges and Coupland in their work on pneumonia (2d ed., 1890) give the figures above quoted.

² Sturges and Coupland, *loc. cit.*

³ *La Sperimentale*, Aprile-Maggio, 1890.

The present views concerning the bacteriology of pneumonia may be summed up in the following conclusions of Sturges and Coupland:

"1. Pneumonia is a specific general disease of which lobar inflammation of the lung is the local manifestation.

"2. The most constant cause of pneumonia is Fraenkel's diplococcus, but there are other viruses which may evoke it.

"3. Chill and other causes, some more, some less distinctly observed in that relation, are to be regarded only as secondary or predisposing.

"4. The 'pneumonic virus' may, and often does, excite inflammatory disturbance in other organs than the lung, and sometimes such inflammations may be excited without the lung participating."

Pneumonia resembles erysipelas in that one attack affords no protection against subsequent attacks.—H.]

DIAGNOSIS.—Acute pneumonitis in some cases is accompanied by symptoms which are highly distinctive. If a patient be seized with a chill followed by febrile movement, together with a pleuritic stitch referred to a circumscribed space near the nipple, and the characteristic rusty expectoration occur, the diagnosis is readily made without the aid of physical signs. But these symptoms are by no means constantly present. The disease is not infrequently entirely latent as regards diagnostic symptoms, and it is often overlooked by those who do not employ physical exploration. Even if its existence be revealed by symptoms irrespective of signs, the situation and extent of the affection can only be ascertained by means of the latter. With the aid of signs the diagnosis in the great majority of cases is made without difficulty. The diagnostic symptoms are especially liable to be absent and the disease to be developed insidiously when it is associated with other diseases. Not infrequently an examination of the chest reveals its existence unexpectedly. I have been accustomed to characterize it under these circumstances as *sneaking pneumonia*, using the language of personification which is so often used in speaking or writing of diseases. The term "asthenic pneumonia" has been applied to it when the symptomatic characters which belong to typical cases are wanting. On the other hand, the term "frank pneumonia" is often used to distinguish cases in which these characters are well marked.

Patients with this disease do not always take at once to the bed. It is not very uncommon to meet with cases in dispensary practice, the disease having gone on to the second stage. These may be distinguished as "walking cases." A young woman once consulted me at my house, complaining chiefly of weakness and loss of appetite, with a slight cough. The temperature in the axilla was 103°, and physical exploration showed solidification of the entire lower lobe of the right lung. She had taken a long drive the previous day, thinking it might be of benefit to her, and she had come two miles to see me. The history rendered it certain that the disease was acute lobar pneumonitis.

In the first stage the signs on which the diagnosis is to be based are slight or moderate dullness on percussion and the crepitant râle. The latter, if persistent and well marked, is almost pathognomonic. Care must be taken, however, not to confound this râle with the subcrepitant, its distinctive characters being its fineness, dryness, and limitation to inspiration. With a distinct appreciation of these characters it should never be confounded with the so-called subcrepitant râle, which, however fine, is a moist, bubbling sound, and liable to be heard in expiration as well as in inspiration. Care must be taken not to mistake for the crepitant râle the sound produced by movements of the stethoscope on the chest if covered with hair, and the crepitus of a fractured rib. It is also to be borne in mind that after rising to the sitting

posture a feeble patient with any disease may furnish for a few deep inspirations a true crepitant râle on the posterior aspect of the chest. But the crepitant râle is not uniformly present in lobar pneumonia. In its absence a positive diagnosis may require some delay until a sufficient number of lobules are solidified to give rise to an appreciable modification of the respiratory murmur. The modification is that which I have described under the name broncho-vesicular respiration¹—a modification approximating, more or less, toward the bronchial or tubular respiration. With the occurrence of this modification the dullness on percussion becomes more marked. In most cases, if the disease be observed from the beginning, the signs of the second stage are soon declared. In hospital practice and in many cases in private practice the disease has already advanced to this stage when the patient is first examined.

When the solidification is sufficient in degree and has extended sufficiently over the affected lobe to furnish the signs of that condition, the diagnosis, if it have not been already fully made, is rendered clear by the presence of these signs. Bronchial respiration, bronchophony, and whispering bronchophony are the signs denoting the condition of solidification. They are first manifested over a limited portion of the affected lobe, and are thence diffused over its whole extent, either quickly or gradually according to the rapidity or slowness with which the whole lobe becomes solidified. The progress of the second stage may be determined by the extension of these signs. They are generally all present, but if one be wanting the others will be likely to be present. It is exceedingly rare for all to be absent. Dullness on percussion is now marked, amounting perhaps nearly or quite to flatness. This dullness or flatness extends over a space corresponding to that occupied by the solidified lobe; or, percussing anteriorly, the boundary-line separating the dullness or flatness from the pulmonary resonance is found to pursue a course coincident with the situation of the interlobular fissure—namely, obliquely upward and outward from the fourth or fifth costal cartilage toward the axilla. And this boundary-line is the same whether the patient be sitting or lying upon the back. This is assuming that the pleural cavity does not contain liquid, which is ascertained by the signs indicated in connection with the diagnosis of simple pleuritis. The crepitant râle, if it have existed in the first stage, may continue, more or less diminished, during the second stage, or it may disappear after the affected side has become solidified. The moist and dry bronchial râles are liable to be heard in this stage.

The invasion of a second or third lobe is denoted by dullness on percussion and the auscultatory signs of solidification, the crepitant râle rarely occurring in the lobes which become secondarily attacked. By means of the signs of solidification—namely, broncho-vesicular and bronchial respiration, and bronchophony with the loud and whispered voice—the extension of the affection to other lobes in addition to the one first invaded is speedily ascertained. If the upper lobe become solidified, it is sometimes flat on percussion, and sometimes it yields a tympanitic resonance which occasionally has an amphoric intonation.

The beginning of resolution and its progress from day to day are shown by modifications of the signs denoting solidification. The bronchial respiration gives place to the broncho-vesicular, and the latter progressively approaches more and more to the normal vesicular murmur, into which it becomes finally merged when the resolution is completed. The characters of bronchophony are gradually lost. Dullness on percussion becomes less and less marked, but

¹ Vide *Physical Exploration of the Chest and the Diagnosis of Diseases affecting the Respiratory Organs*, 2d ed., 1866; also, *Manual of Auscultation and Percussion*, 3d ed., 1885.

some degree of dullness over the affected lobe or lobes continues for some time after the auscultatory signs show the exudation to have been removed. During the progress of resolution the subcrepitant râle is frequently heard, and sometimes the crepitant râle reappears, constituting the *crepitant râle redux*.

If the disease pass into the stage of suppuration, the dullness or flatness on percussion continues, and the moist bronchial râles, due to pus in the air-tubes, are prominent. The auscultatory signs of solidification continue, but are less marked. If abscess of the lung take place, and the patient's life be prolonged until a discharge of the pus into the bronchial tubes occurs, cavernous respiration may become well marked.

[The diseases which most resemble pneumonia, so far as the physical signs are concerned, are sharply-defined phthisis, especially of the apex, hemorrhagic infarction, and œdema pulmonum. They may all be distinguished with readiness if careful attention be paid to the history of the case and the condition of the heart, blood-vessels, and kidneys.

Central or latent pneumonia may be confounded in its early stages with typhoid or typhus fever, but daily physical examinations will sooner or later reveal the signs of pneumonia if this disease is present. Herpes labialis tends strongly to exclude typhoid fever and to corroborate the diagnosis of pneumonia.—H.]

The occurrence of suppurative pleuritis is shown by the signs of that affection. With this complication, the affected side may be dilated, the intercostal depressions are obliterated, and obvious contraction of the chest may follow recovery.

PATHOLOGICAL CHARACTER.—Acute lobar pneumonitis, in the nosological systems of the present as of past time, is placed among the local diseases, and in regard to certain questions it has been regarded as the type of a purely inflammatory affection. This view of its pathological character is now held to be erroneous. The pulmonary affection is doubtless inflammatory; but it is the local manifestation or the anatomical characteristic of an infectious febrile disease, sustaining to the latter a relation analogous to that which the affection of the solitary and agminated intestinal follicles sustains to typhoid fever. If this doctrine be true, the proper place for the disease in the nosology is among the essential fevers. It is here retained in the class of diseases of the respiratory system for convenience of reference so long as its claims to be transferred to the division of the general diseases are not generally recognized. The name acute lobar pneumonitis denotes only a local inflammatory disease. A more correct name is pneumonic fever (*febris pneumonica*)—a name used by the older writers, and corresponding to the popular term "lung fever" formerly in vogue in some parts of this country.¹

Assuming that there are grounds sufficient for adding to the list of essential fevers *febris pneumonica*, or pneumonic fever, we may define the disease as follows:

It is a fever characterized anatomically by an abundant exudative deposit in the air-vesicles of a single lobe, or of two and sometimes three lobes of the lungs, with, in general, circumscribed bronchitis and dry pleurisy. It is a fever which rapidly reaches its maximum intensity, and has a short career the duration averaging about eleven days. It proves fatal chiefly in consequence of associated diseases, complications, or accidents, and in the mode of dying asthenia usually predominates. It depends on a cause or on causes specific in character, of which the most frequently operative is the "*diplococcus lanceolatus capsulatus*" of Fraenkel. It sometimes aborts spontane-

¹ The grounds for holding this doctrine were embodied by me in a paper published in the *Transactions of the New York Medical Society* for 1877.

ously, and it is in some instances arrested by remedies. If not arrested, it may be favorably modified, its duration abridged, and the danger to life diminished by treatment addressed not so much to the pulmonary affection as to the fever.

PROGNOSIS.—The prognosis in cases of acute pneumonitis will depend on the extent of lung involved, the intensity of the pyrexia, the diseases with which it may be connected as an intercurrent affection, its complications, the previous constitution of the patient, etc. These circumstances will affect the gravity and danger to such a degree that, in respect to the probable termination, cases differ as much as if they were cases of different diseases. Occurring as a primary disease, limited to a lower lobe, remaining uncomplicated, and the person affected having a fair constitution, the intrinsic tendency is to recovery; indeed, recovery is not only the rule, but the exceptions are exceedingly infrequent. Of the 133 cases which I have analyzed, in only 2 of the fatal cases was the disease limited to one lobe and not complicated or associated with other important affections. In one of these two cases the inflammation was seated in an upper lobe and eventuated in abscess. In the other case the absence of complications was predicated on the examinations during life, a post-mortem examination not having been made.

Even if more than one lobe be involved, provided the disease be primary and uncomplicated, a favorable termination may reasonably be expected in a subject not enfeebled by age or other causes. I have known recovery to take place in a case in which an entire lung was involved and the patient situated under as unfavorable hygienic circumstances as could well be imagined. In the case referred to the patient was attacked when working alone in a shanty during the winter season in the swamp near New Orleans, there being at the time two inches of water on the ground. After the attack he was unable to leave the bed for any purpose for a week, and during this time he was entirely alone. He had a quart of brandy, which he drank during the week. His habits, as he stated, were temperate. At the end of a week he was visited by some one (not a physician) who gave him thirty grains of calomel. After this he remained alone for ten days. A friend at length came to him, gave him some doses of quinia, and removed him first to his own house and afterward to the Charity Hospital of New Orleans. The physical signs on his admission into the hospital showed pneumonitis affecting the whole of the right lung, and resolution progressing. He remained in hospital six days, convalescence going on rapidly, and at the end of that time he was well enough to be discharged.

I have reported another case in which the patient for four days after the attack remained without food or drink in a lumber-yard, with no shelter but a pile of boards. During this time there was a snowstorm and the temperature was as low as 10° F. On the fourth day he was admitted into Bellevue Hospital. The physical signs showed solidification of the lower lobe of the left lung. On the fourth day after his admission defervescence occurred, and four days afterward he was up and dressed.

The gravity and danger, then, in cases of this disease proceed not so much from the disease *per se* as from coexisting affections and other incidental circumstances. Developed in the course of continued fever, measles, or other diseases, it may lead to a fatal termination. In aged and feeble persons it may end fatally without any coexisting disease, especially if more than a single lobe be involved. Occurring in persons affected with organic disease of the heart, it is likely to prove a serious affection. I have known it to destroy life in the first stage when developed in this connection. The pul-

monary symptoms are rendered more severe and the danger is increased by antecedent emphysema.

Complications which are likely to render it fatal are pericarditis, intermittent fever, and delirium tremens. These complications invest cases with much gravity and danger, but recovery takes place in a certain proportion of cases notwithstanding their existence. An occasional complication to be included in this category is acute diffuse nephritis, as shown by the presence in the urine of albumen, tube-casts, and blood. In drunkards an occasional fatal complication is cerebral meningitis. The gravity and danger from all these complications are of course greater if the disease invade more than one lobe.

There is a liability in the course of this disease to an occurrence which claims especial notice—namely, coagulation of fibrin in the right auricle or ventricle; that is, to heart thrombus. This is of not infrequent occurrence in fatal cases of pneumonitis. It occurs especially when an entire lung becomes involved, and in cases of double pneumonitis. In such cases the obstruction to the passage of blood through the lungs, caused by the presence of the exudation, involves an over-accumulation of blood within the right cavities of the heart. The right ventricle and auricle are enfeebled by distension, and this condition, in conjunction with hyperinosis, leads to coagulation. On examination after death, in the right ventricle is a dense thrombus devoid of red corpuscles, closely intertwined with the tendinous cords and adherent to the ventricular walls. The formation of such a thrombus may sometimes be determined with much confidence during life. In a case presenting no symptoms which denote imminent danger a sudden change takes place for the worse; the circulation is notably disturbed, as shown by the frequency, feebleness, and irregularity of the pulse; there is a sense of the want of air; the expression is haggard and anxious; cyanosis is more or less marked; the patient falls speedily into a moribund state; and this unexpected change is not connected with an extension of the disease to a new lobe or any newly-developed inflammatory complication. Under these circumstances the formation of a heart-clot is highly probable. The probability of this accident is rendered stronger if a newly-developed cardiac murmur be discovered and referred to the right side of the heart; and it is sometimes practicable to appreciate the absence of the tricuspid valvular element of the first sound of the heart.¹

The invasion of a second lobe in a feeble subject may be accompanied by notable prostration, amounting sometimes to a state of collapse. In the previous editions of this work the synopsis of a case was given in which the patient was apparently moribund, restoration taking place under the free administration of alcohol. I have met with cases in which a primary invasion occurring in aged persons produced such a degree of prostration and disturbance of the heart's action that death by rapid asthenia seemed imminent, life being apparently saved by free alcoholic stimulation.

As regards anatomical changes pertaining to the lungs, gangrene, abscess, and the stage of purulent infiltration render the prognosis extremely unfavorable. Yet I have known recovery to take place in cases in which the symptoms denoted the occurrence of these events.

Symptoms which are unfavorable as prognostics are the following: Frequency and feebleness of the pulse; great frequency and labor of respiration; lividity of the prolabia and face; an abundant purulent or muco-purulent expectoration; bloody, dark-colored sputa, commonly known as the prune-juice expectoration; active, violent delirium; low, muttering delirium, with

¹ For cases of thrombosis of the right side of the heart, with remarks, vide *Clinical and Pathological Observations in India*, by Sir Joseph Fayrer, p. 95 *et seq.*

prostration and subsultus tendinum, constituting the typhoid state. Cases presenting the symptoms last stated are often distinguished as cases of typhoid pneumonitis.

In the majority of fatal cases of acute pneumonitis death takes place by asthenia in combination with apnoea, the former predominating. Death purely by apnoea may occur if two or three lobes become rapidly involved, but its occurrence is rare. The occurrence of an abundant pleuritic effusion increases the danger from apnoea. So also does the occurrence of the disease in persons affected with emphysema and in cases of pertussis. Œdema of the portions of lung not affected by the pneumonia (collateral œdema) is an immediate cause of death by apnoea in some cases. This may be an inflammatory œdema, or, when general, it occurs, according to the experimental observations of Prof. Wm. H. Welch, when the left ventricle of the heart becomes disproportionately weak as contrasted with the right ventricle. In general, life is not lost in consequence of the extent of interference with respiration, but, owing to concomitant affections or other circumstances, the vital powers give way and the patient dies from exhaustion or heart-failure. This is an fact important in its bearing on therapeutical indications.

When convalescence takes place, it generally progresses until the recovery is complete. The disease never becomes chronic, unless it may be so considered when resolution is extremely slow. Exceptionally, instead of resolution being completed within a few days, it persists for several weeks, recovery at length taking place. A relapse never takes place. It is rare for phthisis to become developed as a sequel of lobar pneumonitis. When phthisis appears to be a sequel, it probably existed prior to the pneumonitis. If the upper lobe be primarily attacked, it has been supposed that the prior existence of phthisis may be inferred. There may be some ground for this inference, but I have often known the inflammation to be limited to the upper lobe in cases in which the anterior and subsequent history furnished no evidence of phthisis.

CHAPTER V.

PNEUMONITIS (CONTINUED).

Treatment of Acute Lobar Pneumonitis.—Lobar Pneumonitis in Children.—Lobular Pneumonitis.—Atelectasis.—Suppurative Pneumonitis.—Embolic Pneumonitis.—Abscess of the Lung.—Pneumonokoniosis, Anthracosis, etc.—Brown or Pigment Induration of the Lungs.—Hyperæmia of the Lungs.—Hypostatic Congestion.—Hypostatic Pneumonitis.—Pleurodynia and Intercostal Neuralgia.

THE different stages of acute pneumonitis furnishing different therapeutical indications, the treatment of each stage is to be considered separately.

The question whether the disease may be arrested relates to the first stage. Measures which have heretofore been considered as abortive are bloodletting, cathartics, and other remedies entering into the so-called antiphlogistic method of treatment. Experience has abundantly shown that these measures cannot be relied upon for the arrest of this more than of other inflammations. Admitting that they sometimes succeed, the probability of success is not suf-

sufficient to warrant their employment under circumstances which will be likely to render their operation hurtful should they not prove successful. Full doses of quinia—that is, from 20 to 40 grains—given either at once or within eight or ten hours, may arrest the disease. This statement is based on my own experience as well as on the testimony of others. If a patient be seen in the first stage, an effort should be made to render the disease abortive by means of this remedy, inasmuch as it does no harm, aside from the annoyance of cinchonism, if it do not succeed; on the contrary, a favorable influence upon the course of the disease is produced either by its antipyretic effect or in other ways when it fails as an abortive remedy. The disease sometimes aborts spontaneously; that is, without treatment. A few instances have fallen under my observation. The probability, however, of the abortion occurring spontaneously is so slight that if in several cases it follow treatment employed for that end, it may fairly be considered as a successful result of such treatment. Rational objects of treatment, exclusive of that employed for an arrest of the disease in the first stage, are to lessen the intensity of the inflammation, to lower the temperature of the body, to relieve pain, and to promote toleration of the disease.

As regards bloodletting, irrespective of its employment as an abortive measure, it is admissible in certain cases as a palliative, and perhaps to some extent a curative measure, in view of the promptness of its operation. The circumstances which warrant its employment are—high fever, the pulse more or less resisting compression, or, in other words, arterial tension and a robust constitution. It is contraindicated whenever the fever is not high, when the pulse is frequent and weak, and when the patient is anæmic or has a feeble constitution. The relief of pain and embarrassment of breathing by bloodletting is often immediate and marked. The efficiency of this measure as a palliative is due in part to its effect on the general circulation and to the diminution of the functional labor of the lungs; but the relief may be in part explained by the effect in diminishing congestion of the portions of the pulmonary organs not inflamed (the collateral fluxion of Virchow), and also by the effect in lessening the accumulation of blood in the cavities of the right side of the heart. In most of the cases, however, in which the same ends can be secured by other means than bloodletting, the former are to be preferred. These consist in depletion by saline purgatives and in sedative remedies. After the operation of a saline purgative, if the skin be hot and the pulse frequent, tartar emetic or some antimonial preparation may be given as a nauseant sedative; but the doses should not be carried to the extent of producing marked or distressing nausea. The veratrum viride may be given under the same restriction. In this country not a few practitioners regard this remedy as possessing notable curative as well as palliative efficacy. These remedies are contraindicated by feebleness or a tendency to depression. Aconite is an effective sedative remedy, and is to be preferred to the sedatives just named whenever it be desirable to avoid the depressing effects of the latter. Opium may be given with propriety and advantage in the first stage in doses sufficient to relieve the pain and tranquillize the system. Blisters are injudicious, but dry cups, sinapisms, or stimulating liniments may be employed. Stupes or warm fomentations applied to the chest are useful. In many cases a saline purgative followed by some form of opium, the latter continued at intervals, together with soothing applications to the chest, will meet the indications pertaining to the first stage. German authors extol cold applications over the part of the chest corresponding to the affected portion of the lung by means either of napkins which have been dipped in cold water, and which are to be renewed every five minutes, or the ice-bag. It is stated that after a few hours

patients are sensible of relief, and often both the respiration and the pulse become less frequent. Not infrequently the temperature of the body is notably reduced. [Dr. D. B. Lees of England has reported marked success from the application of ice-bags to the chest, and his statements have been confirmed by Goodhart and others. The effect of such applications is not only to relieve pain and diminish pyrexia; in addition, they appear to limit, and sometimes even to abort, the inflammatory process.—H.] In some cases, however, patients complain of the application, and if so it should not be continued. It by no means follows that because warm applications are useful the application of cold is not also useful, or *vice versâ*; either may have a favorable effect, the *modus operandi* of each differing from that of the other. Warm applications soothe and act as revulsives; the application of cold diminishes the determination of blood to the part and relieves pain by obtunding the sensibility.

If the fever be high, as denoted by a temperature of 103° or more, antipyretic measures are indicated, as in the diseases which are generally recognized as essential fevers. These measures are the employment of cold for the direct abstraction of heat from the body and the administration of quinine in full doses, the latter often antagonizing an excessive production of heat. Antipyrine may be substituted for quinia if the latter be not well tolerated or if it prove inefficacious. [This and other similar antipyretics should, however, be employed with great circumspection and only in comparatively robust individuals. They tend to produce cyanosis and collapse—the very symptoms which, in pneumonia, are of the gravest import.—H.] Cold may be employed by means of the bath, the wet sheet, or sponging the body. Of these different modes, the two latter are less inconvenient both for the patient and others than the first, and the last mode will in most instances suffice. The object is to reduce the temperature to as near the normal maximum as practicable. Whenever, after this object is effected, the temperature rises, cold is to be again applied. It is desirable that the employment of these measures be under the personal direction of the physician or an experienced assistant. An alcoholic stimulant should be given whenever the bath, the wet sheet, or sponging is employed. My own practical knowledge of these measures in this disease is not large, but as far as it goes it is confirmatory of their safety and usefulness.¹ They are opposed by existing popular notions; hence in private practice patients submit with reluctance at first, and the physician incurs a risk of being blamed if the cases do not do well. These difficulties are not in the way of the use of quinia and other antipyretic drugs. Quinia is the most efficient of these. It should be given in the same way as with reference to an abortion of the disease. This remedy may suffice for the antipyretic object, rendering the cold-water treatment unnecessary, and it may be conjoined with the latter. Exposing the surface of the body to cool or cold air is not without considerable antipyretic effect, and is unattended by any risk, although from prevalent ideas it seems hazardous to the minds of most persons. The axiom that patients with fever do not “take cold” is one which it is extremely desirable should become popularized. Popular apprehensions on this score often stand in the way of proper ventilation in cases of disease.

The treatment in the second stage has reference to the promotion of resolution, palliation of symptoms, and supporting the powers of the system. Blood-letting in this stage is not admissible, and depletion by means of salines is not

¹ For report of cases treated by the wet sheet by the author, vide Gaillard's *Medical Journal*, March, 1881; also, *Transactions of the New York State Medical Association*, vol. ii.

called for. It is not an object to divert the blood from the solidified lung, for the exudation has already deprived it of blood, and the amount of exudation involves the withdrawal from the blood of a pound or more of solid matter even when the inflammation is limited to a single lobe. Hyperæmia of the lung on the unaffected side (collateral fluxion), with œdema, occurs less often, as it seems to me, than has been supposed. It is indicated by increased frequency of the respirations and dyspnoea, accompanied by the development of fine, moist râles over the unaffected side. The application of a considerable number of dry cups over the chest is the most effectual measure for relief. Experience has shown the inutility of remedies formerly employed as sorbefacients—namely, tartar emetic in large doses and mercury.

Repeated applications of the tincture of iodine will secure a sufficient amount of counter-irritation if any be desirable. Blisters are not advisable, on account of the general disturbance which they are liable to occasion and their interference with physical examinations of the chest. If pain and soreness continue in this stage, stupes with warm water only or with some stimulating liquid, as the liniment of turpentine, will afford relief. The latter will not be required if the tincture of iodine have been applied.

Opium is a valuable remedy in the second as well as in the first stage. It is indicated not only by the continuance of pain, but by vigilance, restlessness, and symptoms denoting constitutional disturbance. I have repeatedly observed a rapid and notable diminution of the frequency of the pulse and of the respirations, with refreshing sleep and a condition of comfort, to follow full doses of opium. The free use of opium does not delay the beginning or retard the progress of resolution. An accumulation of mucous secretion in the bronchial tubes contraindicates the use of opium in full doses.

Remedies to promote expectoration, as a rule, are not indicated. The use of remedies of this class is based on the erroneous idea that the matter of exudation is expectorated. Clinical observation shows that the removal of this matter may go on with great rapidity without any expectoration. The expectoration in the second stage of the disease is due to bronchitis limited to the affected lobe or lobes. The mucous products rarely accumulate in the bronchial tubes to an extent to occasion inconvenience, except as a consequence of a degree of exhaustion sufficient to render the muscular power inadequate to efficient efforts of expectoration; and under these circumstances expectorant remedies will not afford relief.

Sedative remedies, such as aconite and the veratrum viride, are admissible in this stage if there be considerable or high fever without a tendency to asthenia. They should be cautiously given, so as not to incur risk of constitutional disturbance or depression. A high temperature in this as in the first stage calls for antipyretic treatment, and the same measures may be employed. These measures are indicated whenever the thermometer shows a temperature at or above 103°.

To support the powers of life is the leading general indication in the second stage. Resolution will be sure to begin and continue if the life of the patient be sufficiently prolonged. The danger is generally, not from the amount or persistence of the solidification of lung, but from failure of the vital powers before the resolution takes place. This disease belongs among those distinguished as self-limited; if uncomplicated and not attended by accidents, it runs a definite career ending in restoration, provided the powers of life hold out. These considerations, together with the results of clinical experience, enforce the importance of the supporting treatment.

The indication for supporting measures as regards urgency varies much in different cases. In general terms, it is urgent in proportion to the danger from asthenia. It should govern the treatment in cases sometimes character-

ized as asthenic, and whenever there are grounds for distrust of the adequateness of the vital powers to carry the patient safely through the disease. It is a serious mistake to defer supporting measures until the symptoms denote imminent danger from failure of the powers of life. If deferred so long they will probably be too late. The observing and skilful practitioner will foresee and endeavor to forestall a degree of prostration attended with imminent danger. The constitution of the patient, his previous health, and his habits are to be taken into account in judging early of the ability to sustain the disease. Other things being equal, in a warm climate patients are less able to sustain the disease than in cold or temperate climates; supporting treatment, therefore, is oftener and earlier called for in the former than in the latter. In cases which are distinguished as asthenic and typhoid the reliance for successful management must be on supporting measures. These views are the more to be impressed because it is undoubtedly true that until lately the minds of medical men have been so much occupied with the means of subduing inflammation as to overlook the fact that means employed for this end not only often conflict with those which are more important for recovery, but may be positively injurious, if not, indeed, destructive to life. The attention has been directed too much to the disease and too little to the patient.

The supporting treatment embraces tonic remedies, alcoholics, and nutritious diet. Of tonic remedies, quinia is to be preferred. Alcoholics form an essential part of the supporting treatment, as in all other diseases whenever the object is to keep the patient alive until the disease has reached the end of its career and advanced into the stage of resolution. The principle is the same as in other essential fevers; and here, as in the management of the latter, alcoholics are indicated to an extent commensurate with the danger from failure of the vital powers. In certain cases of pneumonitis, as in typhus or typhoid fever and other diseases, there is often a remarkable tolerance of alcohol, and the only guide as regards quantity is the effect as manifested by the symptoms. No abstract rules can be laid down as applicable to all cases, but careful observation must furnish the rule proper to each individual case. Here, too, as in the continued fevers, because alcoholics are vastly important in some cases it is not to be inferred that they are invariably indicated or that they can never do harm; on the contrary, if pushed to an injudicious extreme they are potent for evil, as they are potent for good when judiciously used.

As regards the circumstances under which the use of alcoholics is to be begun, they are always indicated as soon as evidence appears of any tendency to failure of the powers of life. And of this the action of the heart, as represented by the pulse and by the systolic sound over the apex, is the criterion. Feebleness, great frequency, and a pulse vibratory or thrilling but compressible, denoting increased activity but diminished power of the ventricular contractions; also, feebleness of the first sound on auscultation over the apex, and, in addition to feebleness, the shortness and valvular quality of this sound,—these are the characters which indicate supporting measures, of which alcoholics are an essential part. Given at first in small or moderate doses, the effect is to be watched, and the quantity increased in proportion to the urgency of the indication. The habits of the patient as regards the habitual use of alcoholic drinks are of course to be taken into account. Whenever the question arises in the management of a case whether alcoholics be advisable or not, it should be borne in mind that to begin earlier than they are required is far preferable to subsequent delay; for with proper care they can be suspended without any injury having been done, whereas the time lost by beginning too late cannot be regained.

Alimentation is an essential part of the supporting treatment. It is as

important to nourish patients affected with pneumonitis as those affected with any febrile or other disease whenever there is danger from failure of the vital powers. The statement that patients with pneumonitis should be encouraged to take nutritious food during the whole course of the disease is based on considerable experience, and alimentation should enter into the treatment in proportion as the symptoms denote a tendency to asthenia. Milk with farinaceous substances and animal broths should form the diet, thus combining a proper variety of alimentary principles. The desires and taste of the patient may generally be trusted.

These remarks on the supporting treatment are not specially applicable to pneumonitis, but apply alike to cases of any disease the gravity or danger of which is manifested by symptoms denoting failure of the vital powers, and they will be referred to in connection with the treatment of other affections. As applied to pneumonitis, they relate chiefly to cases in which this disease is rendered grave or dangerous either by the extent of lung involved or by coexisting affections. It will be borne in mind that in a large proportion of the cases in which the disease is limited to a single lobe and disconnected from other affections there is little or no intrinsic tendency to a fatal termination. In such cases no active treatment is required, either with a view to lessen the intensity of inflammation or to support the powers of the system; patients pass through the disease satisfactorily under simple palliative measures. I have treated many cases simply with attention to hygiene. It by no means follows that because this disease exists remedies are to be employed; they are to be employed only when there are indications calling for therapeutical interference.

In cases of pneumonitis associated with intermittent fever quinia should be given promptly and in efficient doses. The paroxysms should be arrested as speedily as possible, as the patient may be placed in great danger by their repetition. In a malarial region, or if the patient have been subject to intermittent fever, it is judicious to forestall the possible development of the latter affection by moderate doses of quinia. The malarial cachexia impairs the power of resisting the disease; hence it is more likely to prove fatal in malarial regions, even when uncomplicated with intermittent fever.

Cases of pneumonitis complicated with delirium tremens call for the pretty free use of opium, together with alcoholics and a nutritious diet. [Under these circumstances great benefit may also be derived from the judicious employment of paraldehyde, chloral, and potassium bromide.—H.] Delirium and vigilance, if protracted, are likely to lead to a fatal termination. Pericarditis as a complication adds greatly to the gravity and the danger, but by perseverance in the judicious employment of supporting measures the patient may be carried safely through this combination of diseases. The occurrence of gangrene furnishes an additional indication for support. Pneumonitis occurring in connection with the continued or the eruptive fevers generally gives rise to the indications for supporting treatment.

During the progress of resolution the principles of treatment which have just been presented are applicable until the improvement in the local and general symptoms, in connection with the physical signs, denote convalescence. When convalescence is established, as already stated, there is no danger of a renewed attack. There is, therefore, no need of extreme precautions in order to prevent a liability to relapse. Experience shows that a solid, substantial diet may be entered upon as soon as the patient is fairly on the road to recovery, and that the recovery is more rapid than if the appetite be too much restrained. As a rule, ordinary wholesome, digestible articles of food may be allowed when they are desired by the patient. Permitting or encouraging the patient to sit up will be found not to retard recovery, but,

on the other hand, apparently to hasten the progress of resolution. Early going out of doors is not objectionable.

If the disease proceed to the suppurative stage, purulent matter being either infiltrated or forming abscesses, the prognosis is extremely unfavorable, but perseverance in the employment of supporting measures is sometimes successful. It may be added that timely and efficient support probably affords the best security against suppuration, which happily is extremely rare.

I have for several years advised the carbonate or muriate of ammonia during the progress of the disease with a view to prevent cardiac thrombosis. Of course it is difficult to obtain clinical proof of the protective efficacy of this or any other remedy against that accident. There can be no objection to the use of this remedy on therapeutical grounds, since it does not in any manner affect unfavorably the progress of the disease. Dr. A. Patton of Indiana, in a paper advocating the free use of this remedy throughout the disease—that is, from 5 to 10 grains every three hours—states that of 96 cases in which this constituted all the medicinal treatment, in only 2 cases was the disease fatal.¹ It is probable that digitalis, given with a view to increase the power of the heart's action, is useful in preventing heart-clot. This remedy has seemed to me often signally useful when the action of the heart is feeble or irregular, and also to be of use as a nervous sedative when delirium and vigilance are prominent symptoms.

[Recent experiments of Drs. G. and F. Klemperer are highly suggestive of future possibilities as to the prevention and cure of pneumonia. They found that the rabbit, which is very susceptible to pneumonic infection, could be rendered immune by hypodermic injection of the liquid in which Fraenkel's diplococcus had been cultivated. They soon determined, however, that such injections exerted no curative effect upon the disease. Their next experiments were with the blood-serum of animals upon whom immunity had been conferred in the manner above mentioned, and they were induced to perform them by the discovery of Behring and Kitasato that the blood-serum of animals that had been rendered immune from diphtheria and tetanus exerts a curative effect upon these diseases when induced experimentally. They bled an animal that was proof against pneumonic infection, and obtained from 15 to 20 cc. of serum. They then injected this serum into the venous system of an animal that had been inoculated with the diplococcus and in which the symptoms of pneumonia were well pronounced. The effect was an immediate improvement of all the symptoms and rapid recovery. These experiments were repeated a dozen times, and with similar results in every instance. They finally experimented upon man. In six cases of pneumonia they injected subcutaneously a small quantity of serum from an immune rabbit, and in all the operation was followed by a decided fall in the temperature and a reduction in the frequency of both pulse and respiration.

The pneumonic virus circulates in the blood, and from it or through its effect upon the albumen of the body an antidote—"antipneumotoxin"—is formed which neutralizes the poison and causes the crisis. The Klemperers have isolated the pneumonic virus—"pneumotoxin"—by precipitating an albuminous substance from cultures of the pneumococcus, and the time may not be far distant when its antidote—antipneumotoxin—will be also isolated and dispensed by the apothecary.²—H.]

¹ *Am. Journ. Med. Sci.*, Oct., 1870. Of 207 cases treated chiefly with this remedy by Dr. J. P. Thomas, only 3 were fatal. (Vide *Virginia Medical Monthly*, April, 1880.)

Acute Lobar Pneumonitis in Children.

Acute pneumonitis, the solidification extending over an entire lobe, sometimes involving a second lobe, and presenting after death the anatomical characters which have been described as belonging to this disease in the adult, occurs in young children, although infrequently as compared with its occurrence after this period of life. It is a much graver disease in young children than in adults, proving fatal in a large proportion of cases. From the absence of the subjective symptoms and the difficulty of obtaining physical signs the diagnosis is less easy, and the disease is not infrequently overlooked.

The attack is sometimes ushered in by a convulsion. This may mislead by directing attention to the head. Dulness, drowsiness, or stupor sometimes accompanies the progress of the disease, and these symptoms may mislead in the same way if the symptoms referable to the chest be not marked. Vomiting is not a rare symptom at the onset of the disease. The expectoration, being swallowed, cannot be observed in young children. As regards local symptoms, the disease may be latent in the child, as it not infrequently is in the adult. But in a certain proportion of cases the existence of sharp pleuritic pain is manifested by the expression, and also by the cry in acts of coughing or whenever a deep inspiration is taken. A diagnostic symptom of frequent occurrence is a moaning or grunting sound with the expiratory act. Attention to this symptom is especially important, as it points very strongly to the existence of pneumonitis. Increased frequency of the respirations and dilatation of the nostrils show the existence of some pulmonary affection compromising the respiratory function. The respirations in some cases are very frequent, numbering 40, 50, 60, and sometimes even many more, per minute. One or both cheeks may present a circumscribed flush. If the progress of the disease be unfavorable, lividity of the prolabia and face becomes marked; more or less acceleration of the pulse occurs, and the frequency in some cases is very great, amounting to from 150 to 200 per minute.

When the existence of some acute affection of the chest is declared by the symptoms, the differential diagnosis lies between primary pleuritis, capillary bronchitis, the so-called lobular or broncho-pneumonitis, and lobar pneumonitis. The first of these affections being extremely rare under five years of age, the problem is usually to differentiate the latter from the two other affections. In solving this problem the physical signs are to be relied upon, and the reliance is also upon these for the diagnosis in cases in which the symptoms denoting an acute thoracic affection are not marked. The physical signs are generally available with care and patience, notwithstanding the difficulty of exploring the chest in the young child.

The crepitant râle is oftener wanting in pneumonitis affecting the child than the adult, but it is present in a certain proportion of cases, and is of course to be sought after. This sign belongs exclusively to pneumonitis, whereas fine bubbling (subcrepitant) râles belong to capillary bronchitis. If there be doubt as regards the discrimination between the crepitant and the bubbling râles, it is to be borne in mind that capillary bronchitis is a bilateral disease, and the bubbling râles will be present in both sides; whereas in the great majority of cases pneumonitis in the child, as in the adult, is unilateral, and the crepitant râle will be limited accordingly to one side. Dulness on percussion is readily determinable in the child; and this is an important point in the differential diagnosis. Bronchial respiration and bronchophony may generally be obtained in the child by perseverance in auscultation, the cry answering for the voice. These signs do not belong to capillary bronchitis, and are rarely present in lobular pneumonitis. In short, the diagnosis is to be based on the same signs

as in the adult, but patient efforts may be requisite to obtain them. As regards primary pleuritis, the signs denoting effusion are available in the child as well as in the adult, and their absence warrants the exclusion of that affection.

The treatment of acute lobar pneumonitis in children involves the same principles as the treatment of the disease in adults, with those modifications which therapeutical measures require in their application to infantile life. It is questionable whether bloodletting be ever advisable in young children, even when the diagnosis is clear in the first stage of the disease. As a rule, this measure is not to be employed, and the exceptions to the rule, if there be any, are few; depletion by salines may take its place. Antimonial preparations, if given at all, are to be prescribed with great caution, and in general other and less depressing nauseant sedatives are to be preferred. The *veratrum viride*, if given, should be prescribed in small doses and its effects very carefully watched. *Aconite*, in children as well as adults, is a useful sedative in this affection. Blisters should not be employed. A sinapism or turpentine stupes may be applied to the chest, followed by a poultice or the water-dressing. Particular attention should be given to the latter, in order to see that either the entire chest or the whole of the affected side is covered with several thicknesses of flannel and a layer of oiled muslin. The spongio-piline is a good substitute for the poultice or the water-dressing. Opium need not be withheld, but it must be given with circumspection. Finally, as much depends in severe cases, in the child as in the adult, upon the early, judicious, and persistent employment of supporting measures. In children, as in adults, under certain circumstances there is a remarkable tolerance of alcoholics. I have notes of the case of a child of a medical friend (age fourteen months), presenting the utmost gravity of symptoms, the pulse 200 and the respiration 120 per minute, in which brandy was increased to at least an ounce hourly, and under this amount the pulse fell rapidly to 124 and the respiration to 50 per minute, the carbonate of ammonia and a little morphia constituting the additional treatment. Recovery took place. This case is cited in illustration of the extent to which in some cases the employment of alcoholics may be carried. It does not follow that they are to be generally employed excessively or largely. The same rules are to be observed in their use in children as in adults, with a view, on the one hand, to secure the benefits of alcoholics, and, on the other hand, to avoid the evils of their over-use.

Lobular Pneumonitis—Broncho-pneumonitis—Atelectasis.

Lobular pneumonitis is also frequently called *catarrhal pneumonia*, from the fact that the exudation is chiefly cellular. This latter name, however, is inappropriate, because the term "catarrhal" is only applicable to inflammations of mucous membranes, and the wall of the air-cells and alveolar passages cannot be considered properly a mucous membrane; and, moreover, fibrin is sometimes present in the exudation of so-called catarrhal pneumonia as well as in that of lobar pneumonitis. The name *cellular pneumonia* employed by Virchow is not sufficiently distinctive. The terms *broncho-pneumonitis*, implying the coincident affection of the bronchi and of the air-cells, and *lobular pneumonitis*, signifying the lobular dissemination of the inflammation, are to be preferred.

Lobular pneumonitis is a secondary affection, and almost always secondary to inflammation of the smaller bronchi. It is frequent in childhood, but rare in adults, except in the debilitated and the aged. In the new-born and in very young children it is usually preceded and accompanied by *atelectasis* or collapse of a greater or less number of pulmonary lobules (*apneumatosi*s).

Atelectasis may attend lobular pneumonia occurring later in life, but it is a less constant accompaniment. Portions of the lung-tissue in the condition of atelectasis contain no air; they are non-crepitant and sink in water. They present a bluish-red appearance through the pleura, and a more brownish-red color on cross-section. They have a smooth surface, a firm consistence, and are depressed below the level of the surrounding lung-tissue. They can be inflated by blowing through the bronchi. In many cases, but not always, occlusion of the bronchi immediately connected with the atelectatic spots can be demonstrated. The most frequent source of obstruction is an accumulation of the products of inflammation in the smaller bronchi. The air-cells connected with the occluded bronchi collapse after the absorption of the contained air. Microscopical examination of the collapsed lobules shows distension of the pulmonary capillaries with blood, and the presence of granular, desquamated epithelial cells in the collapsed alveoli. Atelectasis of portions of the lungs may be a *congenital* condition in the new-born and in infants a few days or weeks old, the affected lobules having never been inflated, in consequence either of weakness of the respiratory efforts or of obstruction of the bronchi by mucus, meconium, etc. *Acquired atelectasis* is far more frequent in children than in adults. The name atelectasis is also sometimes applied to the condition called *carnification* of the lungs, the air having been expelled by pressure from without as by an extensive fluid accumulation in the pleural cavity. Atelectasis of whatever form is more frequent in the lower lobes than in the upper. Single circumscribed lobules may be affected, or even a whole lobe. When there is extensive atelectasis the remaining parenchyma of the lung is usually in the condition of vicarious vesicular emphysema.

There has been much controversy as to the relations between atelectasis and lobular pneumonia. Formerly, writers regarded atelectasis as congenital pneumonia, and since the true nature of the condition has been recognized it has usually been held that collapse of the air-cells in itself leads to the development of lobular inflammation. It is probably not correct to regard either acquired pulmonary collapse or a persistence of the foetal state of the lungs as alone a cause of inflammation. We may consider that lobular pneumonia occurs only when there is present within the alveoli an irritant capable of inducing inflammation. Most foreign particles, and particularly the stagnating secretion of the inflamed bronchial mucous membrane, are irritants capable of exciting bronchitis and lobular pneumonia by entrance into the small bronchi and the air-cells, whether or not they completely obstruct the bronchi and lead to atelectasis.

The pathological changes occurring in lobular pneumonia have been divided into the same three stages as in lobar pneumonia—namely, first, congestion or engorgement; second, red hepatization; and third, gray hepatization. Such a division is, however, less important and well defined in lobular than in lobar pneumonia. In a typical case of lobular or bronchopneumonia disseminated throughout both lungs are small firm spots varying in size from a pea to a pigeon's egg. The color may be brownish-red, reddish-gray, gray, or yellowish, and the periphery is usually darker than the centre. The surface is lustreless, smooth or slightly granular, and somewhat elevated above the surrounding lung-tissue. The consolidated pulmonary substance is non-crepitant and sinks in water. When the solidified lobules are situated at the surface of the lung the overlying pleura is coated with a delicate layer of fibrin. Usually, drops of muco-pus can be squeezed out of the smaller bronchi. The microscopical examination of the solidified lobules shows the air-cells to be filled, though less distended than in lobar pneumonia, with pus-cells, epithelial cells, and some granular matter in varying proportion. In some cases the pus-cells predominate; in other cases, large

granular cells with vesicular nuclei, thought to be alveolar epithelial cells. Red blood-corpuscles are usually present, but not in such number as in lobar pneumonitis. The presence of large numbers of pus and epithelial cells in the alveoli, the comparatively small number of red blood-corpuscles, and the absence of fibrin may be considered to be the characteristics of the exudation of broncho-pneumonitis as distinguished from the lobar form. Sometimes, however, fibrillated fibrin may be found in the exudation of lobular pneumonitis, and in fact, as far as the inflammatory products are concerned, there is every grade of transition between a typical, purely cellular exudation and the fibrino-cellular and almost hemorrhagic exudation of lobar pneumonitis. Mucus and cells are sometimes inspired from the bronchi into the alveoli. The walls of the inflamed bronchi are often infiltrated with leucocytes. The inflammation may extend by continuity to the air-cells immediately adjacent to these inflamed walls. There may be some dilatation of the bronchi. Various forms of bacteria have been found in the inflammatory exudation in the bronchi and air-cells, and doubtless in many cases bacteria stand in a causative relation to the disease.

There is great variety in the extent of lung involved in the inflammatory process. The pneumonitis may be confined to a few lobules, as, for instance, those surrounding a hemorrhagic infarction or a new growth; there may be countless nodules of consolidation scattered throughout both lungs, or even all the lobules of a lobe may become involved. In the rare cases of lobar consolidation from lobular pneumonitis the fact that the lobules are not simultaneously but successively involved gives to the surface a peculiarly variegated appearance different from that observed in lobar pneumonitis. The surface is also less granular than in the latter disease. As to the origin of the cells which fill the alveoli, it is customary to regard the pus-cells as emigrated white blood-corpuscles. Whether the alveolar epithelium play an active part in the inflammatory process is a matter of dispute. There is no proof of the production of pus-cells from proliferating epithelial cells, and, in those cases in which the number of large epithelium-like cells in the alveoli seems greater than can be accounted for by a mere desquamation of the epithelial lining, it is not necessary to assume active proliferative changes in the epithelium, as it is abundantly proven that wandering leucocytes can become transformed into epithelioid cells.

The most frequent termination of lobular pneumonitis is in resolution. As in lobar pneumonitis, the cell-elements undergo fatty degeneration, and by transudation of serum a kind of emulsion is formed capable of absorption. When the broncho-pneumonia persists for a long time, the alveolar walls usually become thickened by a new growth of connective tissue.

It has been held by most authorities that the inflammatory products of lobular pneumonitis may undergo caseous metamorphosis which leads to the development of pulmonary phthisis. We now know that in such cases infection with the tubercular virus exists. It is probable that in some cases the existence of broncho-pneumonia favors the lodgment and development of the tubercle bacilli. It is, however, an error to confound with ordinary broncho-pneumonia the lobular caseous pneumonia so often found in phthisical lungs. The latter affection is anatomically and etiologically a distinct disease.

CLINICAL HISTORY.—Inasmuch as a bronchitis affecting both sides (bilateral) precedes and accompanies the collapse of lobules in lobular pneumonitis, the symptoms of that disease are always present. As will be seen in treating of Bronchitis in a following chapter (Chapter IX.), the symptoms attributable to the bronchial inflammation vary according to its extension into

tubes of small size. In addition to cough and expectoration, increase in the frequency of the respirations, dyspnoea, and cyanosis may be accounted for by the bronchitis alone if tubes of small size become involved (capillary bronchitis). These symptoms are more marked in proportion to the number of lobules collapsed and inflamed. The symptoms are chiefly due to the pneumonitis if the bronchitis be limited to tubes of large or medium size.

The bronchial inflammation may be acute or subacute. The pyrexia is proportionate to the acuteness of the bronchial inflammation and to the extent of lung affected. This will, therefore, vary considerably in different cases. The symptoms relating to the frequency and other characters of the pulse offer variations dependent on the intensity of the fever and the obstruction to the passage of blood through the pulmonary vessels. Corresponding variations in other constitutional symptoms are incident to the fever and disturbance of the circulation. It follows that broncho-pneumonitis may be a disease of great severity and danger, or it may be comparatively devoid of gravity. Some cases are characterized by notable fluctuations during the course of the disease, owing to an increase at different periods of the number of lobules implicated. The symptoms on successive days may fluctuate, collapsed lobules becoming inflated or an additional number of lobules becoming affected.

DIAGNOSIS.—The diagnosis relates to two factors as regards the symptomatic phenomena—namely, the bronchitis and the collapsed or inflamed lobules. A third factor is the occurrence of emphysematous lobules (lobular emphysema). The physical signs denoting the bronchitis are the moist bronchial or bubbling râles, which are coarse, fine, or subcrepitant according to the size of the tubes in which they are produced. Râles varying in coarseness or fineness may be combined. The collapsed and inflamed lobules may furnish no distinctive signs if in the form of small nodules, disseminated, and about equal in number on the two sides. Broncho-vesicular or bronchial respiration, increased vocal resonance, and bronchophony, together with dullness on percussion within a circumscribed space on one side or on both sides, may be found wherever a sufficient number of lobules in close proximity to each other are affected so as to give rise to solidification extending over a considerable area. Lobar pneumonitis is excluded by the fact that the solidification does not extend over an entire lobe. On the other hand, the signs of solidification show something more than bronchitis, this disease alone not giving rise to these signs. If no signs of solidification be discovered, it is difficult or impossible to differentiate broncho-pneumonitis from bronchitis affecting tubes of small size. In severe cases inspection shows retraction of the lower part of the chest on both sides with the acts of inspiration, and sinking in of the soft parts above the clavicles, as in cases of capillary bronchitis. Emphysematous lobules of the upper lobes will give rise to a vesiculo-tympanic resonance on percussion.

CAUSATION.—Age is to be regarded as the most important element in the causation. The fact that in a very large majority of cases the subjects are either infants or children or persons advanced in years, is probably to be explained by the much greater tendency in bronchial inflammation to extend to the smaller bronchi in the two extremes of life. The affection occurs not infrequently as a sequel of the eruptive fevers, rubeola, scarlatina, or small-pox; also of whooping cough, diphtheria, and, more rarely, of the continued fevers. It may be produced traumatically in persons of any age by the inhalation of chlorine or other gases, of vapors, and of irritating substances of various

kinds. Exposure to the latter causes may be incident to certain occupations. [The question of the relation between lobular pneumonitis and those infectious diseases to which it is so frequently secondary has been much discussed. When secondary to diphtheria, the Klebs-Löffler bacillus has been found in the alveolar products of inflammation, together with the staphylococcus pyogenes aureus et albus, and the question arises as to which is the cause of the pulmonary inflammation. The weight of authority is in favor of the view that the last-mentioned organisms are the exciters of inflammation, for they or similar microbes, such as the streptococcus, are always present, no matter what may be the nature of the primary disease.—H.] The pneumonitis which is liable to accompany exudative laryngitis (croup) in children is a broncho-pneumonitis. Its occurrence in cases of whooping cough is not infrequent. In the insane, the delirious, and the greatly enfeebled, with obtunded sensibility of the air-passages, foreign particles, such as bits of food, the buccal fluids, etc., are likely to be inspired into the small bronchi and air-cells, giving rise to lobular pneumonia, which in these cases may be of a rather diffuse character. This is the deglutition-pneumonia (Schluck-pneumonie) of German writers. Not infrequently the inspired foreign particles are so irritating that the inflamed foci terminate in abscess, and occasionally they lead to gangrene.

TREATMENT.—The therapeutic indications have reference, first, to the bronchitis, and second, to the inflammation and the collapse of lobules. The former are the same as in cases of bronchitis irrespective of the lobular conditions, and they will be considered in a following chapter. The prompt and efficient treatment of bronchitis, especially in the young and old, is important by way of preventing the collapse and inflammation of lobules. [When the physical signs and symptoms denote that the bronchial inflammation has extended to the lung, the chest should be enveloped in a jacket-poultice of linseed-meal, to be renewed as soon as it grows cold. This measure appears to have fallen somewhat into disuse, but is undoubtedly beneficial. When the poultices are finally removed their place should be supplied by absorbent cotton over which is placed a layer of oiled silk or waxed paper. The atmosphere of the sick-room should be charged with moisture with steam from a croup-kettle or other suitable apparatus, and its temperature should not fall below 65° F. nor exceed 70° F. Internally, experience sanctions the use of ammonia, which is least disagreeable to children in the form of the aromatic spirit. It is rarely objected to when given in the form of a "fever-mixture" with a little citrate of potash and liquor ammoniæ acetatis. If the respiration is embarrassed by an accumulation of mucus in the air-passages, the latter should be emptied by means of emetics, of which the best for this purpose is the syrup of ipecac in drachm-doses. Sulphate of zinc and alum may also be employed. Opium should not be administered unless the patient is very restless, and manifestly from pain. Under these circumstances a few drops of paregoric or a drop of the deodorized tincture of opium may be given at suitable intervals to an infant, and in larger doses to older children. Where there is decided pyrexia the patient should be immersed in a warm bath which is gradually cooled down to about 75° F. If this be done in the evening, sleep will be promoted and rendered more tranquil and refreshing. If signs of asphyxia appear, in addition to emptying the bronchi with emetics, the child should be placed in a warm bath and cold water poured over the head. The respiratory centres should also be stimulated by the internal use of strychnia and belladonna. The diet should be nutritious and concentrated, consisting, for the most part, of milk and lime-water, brandy and egg, milk punch, meat-juice, chicken- and mutton-broth, arrow-root and

other farinaceous substances.—H.] The dorsal decubitus should not be constantly maintained, changes of position being important as preventive of collapse of lobules.

Congenital atelectasis in the newly born is denoted by rapid, short acts of breathing, feebleness of the cry, difficulty in nursing from want of breath, and cyanosis. The absence of cough and bronchial râles suffices to exclude bronchitis. Congenital malformations of the heart are excluded by the absence of their physical signs. The respiratory murmur is feeble, especially at the lower and posterior portions of the chest. The lower part of the chest in front is retracted in the act of inspiration.

Inasmuch as the deficient expansion of the lungs is due to weakness of the respiratory acts, the strength of these should be increased by the momentary application of cold water to the chest, exposing the body for a few moments to cold air, and exciting in various ways crying efforts. Care should be taken to free the nostrils and throat from accumulations of mucus.

Suppurative Pneumonitis—Embolic Pneumonitis— Abscess of the Lung.

Suppurative pneumonitis is characterized by the formation of pus and breaking down of lung-tissue. Sometimes the pus infiltrates the walls of the bronchi or of the blood-vessels, or follows bands of interstitial tissue (dissecting pneumonia). The most important form of suppurative pneumonitis is that which results in the formation of abscess. The abscess-cavity usually varies in size from that of a pea to that of a hen's egg, but in some cases the abscess takes in the greater part or the whole of a lobe. The shape of the cavity may be round or irregular. The walls of the abscess are usually ragged. In cases of long standing a fibrous capsule forms around the abscess.

As has already been mentioned, lobar pneumonia and lobular pneumonia rarely terminate in abscess. Abscesses may be produced by the inspiration of foreign irritating particles, as in many cases of deglutition pneumonia (p. 92). Wounds of the lung, especially when attended by the lodgment of foreign bodies, may give rise to abscess. In new-born children there is a form of septic pneumonia which frequently terminates in abscess. In this form of pneumonia an enormous number of micrococci are found in the air-cells. In chronic phthisis suppurative processes in the walls of cavities, and sometimes in other parts of the lung, may be an important pathological element.

The most frequent form of suppurative pneumonitis is that produced by infectious emboli, which cause metastatic abscesses in the lungs. The source of the emboli is usually to be sought in thrombi formed in veins leading from some centre of infection, such as external wounds, inflammation of the uterine veins in puerperal women, bed-sores, abscess of the middle or external ear and of other situations, and ulcerative endocarditis. The embolus brings with it some poison which acts as an intense inflammatory irritant. It is not always possible to find the primary thrombus, nor can an embolus in all cases be demonstrated. It is probable that the poison may be carried by the blood in a finely molecular form. Metastatic or pyæmic pulmonary abscesses vary in number from one to several hundred, and in size from a pin's head to those involving an entire lobe. They may or may not be accompanied by the mechanical effects of emboli; that is, by hemorrhagic infarctions, which are to be described subsequently.

The pleura covering an abscess is inflamed, and there is often a general pleuritis, which may also be of a purulent character. The abscess may rupture into the pleural cavity.

Micrococci are always present in the pus. The same micro-organisms which cause suppuration elsewhere also occasion suppurative inflammation of the lung.

The most important aid in the DIAGNOSIS of abscess of the lung is the examination of the sputum. The color of the sputum is usually yellow, like that of ordinary pus, but it may be green or brownish. The odor is usually somewhat offensive, but it has not the fetor of gangrene. Of the utmost importance is the presence in the sputum of particles of lung-tissue, which can often be detected even with the naked eye. These particles are found by microscopical examination to contain elastic fibres (which are usually absent or scanty in gangrene of the lung), fatty crystals, amorphous pigment, and especially hæmatoidin crystals. Micrococci, which do not stain blue with iodine like certain ones in gangrene, are present in large number. The physical signs of a cavity may be detected if the abscess be of sufficient size, but these signs are not in themselves distinctive of abscess. Other symptoms, such as pain, dyspnœa, pyrexia, rigors, and sweats, are often present. In pyæmia it is generally impossible to disconnect the general symptoms which are indicative of the pulmonary affection from those which belong to the clinical history of pyæmia. In pyæmia it is rare that the different foci of inflammation in the lungs involve areas sufficient to give rise to characteristic physical signs.

The PROGNOSIS is almost necessarily fatal in pyæmic pulmonary abscesses. In other forms of pulmonary abscess, such as that secondary to pneumonia, the prognosis is comparatively favorable—more favorable than in gangrene of the lungs. The affection, however, is in all cases grave.

The TREATMENT is to be directed especially to sustaining measures. Quinine may be given in large doses. The air of the room should be kept pure, and inhalations of antiseptic vapors, such as thymol or carbolic acid, may be tried. A case of large abscess of the lung which was first diagnosed as empyema was treated successfully by Teale by means of incision and free drainage.¹ [When the expectoration is copious, the patient's strength declining, and the physical signs denote that the abscess is superficially seated, the proper treatment is undoubtedly surgical. Nearly 50 per cent. of the recorded cases of pneumonotomy for pulmonary abscess have terminated in improvement or recovery. The following statistics are given by Eichhorst:² Operations, 13; recovery or improvement, 6 (=46.1 per cent.); fatal termination, 7 (=53.9 per cent.). If the operation is not followed by recovery, it may avert the danger of sudden rupture of the abscess into bronchi, pleura, or pericardium or its extension to neighboring organs.—H.]

Pneumonokoniosis—Anthracosis—Siderosis, etc.

Under the generic name pneumonokoniosis, proposed by Zenker, are included the various affections of the lung produced by the inhalation of dust-like particles. A considerable number of such inhalation-diseases is already known. The one longest recognized is the lesion caused by the inhalation of coal-dust. A moderate amount of black coal-pigment is found in the lungs of all adults, more especially of those living in cities; but in the lungs of those who have been exposed for a long time to a dense atmosphere of coal-dust the carbon-particles accumulate to such an extent as to cause a lesion called *anthracosis*

¹ *Lancet*, 1884, vol. i. No. 2.

² *Specielle Pathologie*, Band i. s. 519.

of the lungs. This lesion is produced especially in coal-miners. The particles of coal are carried by the current of inspired air into the air-vesicles or alveoli. Thence, either free or enclosed in cells, which are probably emigrated white blood-corpuscles, they make their way into the alveolar septa, and are still further conveyed through the lymph-spaces and lymph-vessels into the interlobular and peribronchial connective tissue. Some of the particles reach the bronchial glands, and exceptionally may even be carried to the cervical or abdominal lymphatic glands. The lungs and bronchial glands are black; the microscope shows the coal-pigment to be chiefly in the interlobular connective tissue and in the bronchial glands, but it is also present inside of cells in the alveoli and in the walls of the air-vesicles. Extensive anthracosis may exist without any changes in the lung other than chronic bronchitis and the presence of some large cells containing pigment in the alveoli. Frequently, however, it is combined with other chronic inflammatory changes, particularly with chronic interstitial pneumonitis. Dense fibrous bands and nodules deeply pigmented are found. The walls of the alveoli are thick, and their lumina obstructed or even obliterated by the new growth of fibrous tissue. Firm pleuritic adhesions are present. Combined with these chronic interstitial changes bronchiectatic and ulcerative cavities may be present. Anthracotic lungs may be the seat also of chronic pulmonary tuberculosis, in which case tubercles and tuberculous pneumonitis will be found.¹ To pulmonary anthracosis with chronic interstitial inflammation, with or without the presence of tubercles, the name coal-miner's phthisis is applied. The coal-particles, when of sufficient size, can be recognized as such under the microscope; often, however, they are not to be distinguished from melanotic pigment derived from the blood. The coal-particles are often present in the expectoration of those affected with anthracosis pulmonum.

The term *siderosis pulmonum* denotes the accumulation in the pulmonary structures of the oxide of iron. This oxide forms a very fine, brownish-red dust. It is inhaled by workmen employed in dyeing, polishing mirrors, and other mechanical arts in which it is used. Accumulating in the lungs, it causes a reddish pigmentation. Its morbid effects were first studied by Zenker.² They are essentially the same as in anthracosis, the color being red instead of black.

Chalicosis pulmonum is the name given to the pulmonary changes induced by the inhalation of stone-dust. It is also called stone-cutter's phthisis. The chemical examination of these lungs shows the presence of an excess of silica. The changes are similar to those of anthracosis and of siderosis, with the exception of the greater disposition to the formation of nodules and diffuse masses of fibrous tissue. These have a gray centre and dark periphery. The foreign particles can be recognized microscopically, but not so readily as in the previous affections.

Various other forms of pneumonokoniosis have been described, such as those due to the inhalation of particles of tobacco, of cotton, of grain, of various metals, etc.

The clinical history of the different varieties of pneumonokoniosis is that of bronchitis, which is generally chronic, associated, in a certain number of cases, with fibroid phthisis.

¹It is claimed by recent observers that tubercle bacilli are usually absent in coal-miner's phthisis, in which case the process is not to be regarded as tuberculous. According to Cohnheim, coal-particles, as such, cause no irritative changes in the lung, and when inflammatory changes are present irritating substances are inhaled with the particles of coal.

²*Deutsches Archiv f. klin. Med.*, Bd. 2, p. 116.

The removal of the patient from the continued operation of the cause is of course the first object of treatment. In other respects the indications relate to the diseases which are incident to the pneumonokoniosis.

Brown or Pigment Induration of the Lungs.

The lesion thus entitled, described by Virchow in 1847, is referable to the long-continued passive congestion incident to valvular disease of the left side of the heart, particularly to obstruction and to regurgitation at the mitral orifice. Lungs thus affected do not collapse on opening the chest as much as when they are healthy. They are heavy, inelastic, dry, crepitating but little on pressure, of a leathery consistence, and they have a peculiar reddish-brown, yellow, or salmon color. On section, reddish or brown spots may be seen, due to ecchymoses. The microscope shows that the essential morbid condition is a dilatation of the pulmonary capillaries, loops of which often project far into the alveoli and partially obstruct their lumina. The air-cells are still further obstructed by the presence of large epithelial cells containing yellow or brown pigment, which cells may accumulate in sufficient number to fill the alveoli. Pigment is also found within the capillary vessels, in the capillary walls, and in the interstitial tissue, both free and enclosed in cells. The pigment is derived from red blood-corpuscles which escape through the capillary walls by diapedesis, in part also by rupture of the walls. The walls of the air-cells and the interstitial tissue often appear hypertrophied. Rindfleisch describes also an hypertrophy of the smooth muscle-fibres of the pulmonary parenchyma in this affection.

The symptoms denoting the lesion are not definite, but it must increase the dyspnœa which is connected more directly with the cardiac disease. :

Hyperæmia of the Lungs—Hypostatic Congestion—Hypostatic Pneumonitis.

Active congestion or hyperæmia of the lungs, irrespective of inflammation, is rarely if ever a primary morbid condition, and is hardly to be considered as an individual affection. It may be produced by increased power of the heart's action, arising either from transient causes, such as the ingestion of alcoholic stimulants and mental emotions, or from hypertrophy of the right ventricle. It may be caused by the inhalation of stimulating or irritating vapors. Whenever the circulation in a considerable portion of the lungs is interrupted, more or less abnormal determination of blood must take place in the portions to which the flow of blood is unobstructed, as in cases of emphysema, lobar pneumonia, pleuritis, etc.

Passive hyperæmia or congestion is of more frequent occurrence, but is never primary or idiopathic. It is an effect of mitral cardiac lesions causing either obstruction or regurgitation, or both combined. It is also consequent on feebleness of the action of the heart, especially of the right ventricle, as in cases of dilatation or of fatty degeneration, and may be a symptom of asphyxia and of certain cerebral injuries and diseases. In cases of general dropsy it occasions a disproportionate amount of hydrothorax. It gives rise to brown or pigment induration of the lungs. (See p. 96.)

Passive hyperæmia occurring in the dependent portions of the lungs is called hypostatic congestion. The conditions which favor the production of hypostatic congestion are enfeebled heart's action and the maintenance of the body in one position for a long time. It is met with in acute infectious diseases, in the aged, and in the course of chronic diseases which occasion general debility. The higher grades of hypostatic congestion result in a

transudation of bloody serum. The condition of lung thus produced has been called *splenization*. The affected lung-tissue is of a dark-red color, crepitates less than in health, and upon section a large quantity of blood and serum oozes out. In prolonged or in severe hypostatic congestion the so-called hypostatic pneumonia is frequently developed. It has been disputed whether this is to be regarded as an inflammatory affection or not. It seems to involve a low degree of inflammation. The lung-tissue is dark-red, friable, non-crepitant, and sinks in water. The whole lower lobe or only portions of it may be implicated. Microscopical examination shows the pulmonary capillaries widely distended with blood, and the air-cells filled with blood-corpuscles, desquamated epithelial cells, and sometimes fibrin. The inflammatory condition is more analogous to certain forms of lobular pneumonitis than to lobar pneumonitis.

Congestion of the lungs, whether active or passive, compromises the respiratory function—*first*, by diminishing the capacity of the air-cells; and *second*, by lessening the quantity of decarbonized and oxygenized blood returned from the lungs to the systemic circulation. The respirations are increased in frequency, and a sense of the want of air, or dyspnœa, is felt, *cæteris paribus*, in proportion to the degree and extent of the congestion. As regards physical signs, congestion, if marked or considerable, undoubtedly causes a certain amount of dullness on percussion; but this is not determinable if both lungs be alike congested, or in cases in which congestion of one lung follows certain affections in the other side of the chest, as in pleurisy with effusion, pneumo-hydrothorax, etc. Congestion also undoubtedly diminishes the intensity of the respiratory murmur; but if the murmur be changed in character—that is, if it be bronchial or broncho-vesicular—there is solidification from some cause. It is not probable that simple congestion gives rise to adventitious sounds or râles, nor does it occasion any vocal signs.

The TREATMENT of active hyperæmia must have reference, of course, to the causative conditions and the circumstances under which it occurs. The disturbance of respiration, not only when the hyperæmia is bilateral, but when unilateral, as when one lung is consolidated or compressed, may be so great as to call for venesection. In most cases, however, dry cups applied to the chest, revulsives, and cardiac sedatives suffice for relief.

In hypostatic congestion, on the other hand, measures to increase the power of the heart's action are indicated—namely, digitalis, alcoholics, and alimention. As a preventive measure in cases of prolonged disease, especially if the patient be feeble, constant recumbency on the back is to be avoided; the position of the body should be changed at intervals. Deep inspirations from time to time should be enjoined. In this way hypostatic pneumonitis may be prevented. The occurrence of the latter in different diseases not infrequently contributes to a fatal termination. In all diseases accompanied by much prostration or of long duration, or when the subjects are feeble, important objects of treatment are the prevention and removal of hypostasis in the dependent portions of the lungs. These objects are often of prominent importance in cardiac diseases.

Œdema of the lungs will be considered under a separate heading. (Vide Chapter XI.)

Pleurodynia and Dorso-Intercostal Neuralgia.

A brief consideration of these affections is included in this chapter, because, from similarity as regards pain, they are liable to be confounded with either acute pneumonitis or pleuritis. Prior to the employment of physical exploration this mistake was by no means uncommon, and it is still made by those

who depend on symptoms alone. The term *pleurodynia* is applied to a painful affection of the muscles entering into the composition of the thoracic walls. *Intercostal or dorso-intercostal neuralgia* denotes a neuralgic affection of the intercostal nerves.

Both affections may be characterized by pain resembling that of either acute pneumonitis or pleuritis; that is, a lancinating pain felt especially in the act of inspiration. They may be accompanied by a dry cough which is acutely painful. In case of pleurodynia there may be pyrexia, and this may accidentally exist in cases of intercostal neuralgia. How are these affections to be discriminated from inflammation of the pleura either primary or occurring as a complication of inflammation of the pulmonary parenchyma?

Intercostal neuralgia, as a rule, is not accompanied by pyrexia. But this affection has a diagnostic criterion which is readily available. It consists in the existence of tenderness usually in three isolated points—namely, behind, near the dorsal vertebræ; laterally, in one, two, or three intercostal spaces; and anteriorly, in one or more intercostal spaces near the sternum or over the epigastrium. Sometimes tenderness exists in only two of these situations. The tenderness is frequently confined to a very limited space in each situation, a space perhaps small enough to be covered by the finger. On the opposite side of the vertebræ, and between the tender points in the three situations, pressure or percussion is well borne. In addition to this diagnostic test, physical exploration fails to discover the evidence of either pleuritic or parenchymatous inflammation—namely, in primary pleuritis a friction murmur and the signs denoting pleuritic effusion, and in pneumonitis the crepitant râle and the signs of solidification. The affection occurs much oftener on the left than on the right side. Both sides may be affected, but this is extremely rare.

Pleurodynia lacks a similar positive test; that is, the tenderness is not limited to isolated points, but is more or less diffused. The diagnosis, therefore, must rest on the exclusion of intercostal neuralgia by the absence of the evidence just stated, together with the absence of the signs both of pleuritis and pneumonitis. Pain in pleurodynia and intercostal neuralgia is more marked, as a rule, in movements of the body than in the respiratory movements, the reverse being true of the pain in pleuritis and pneumonitis. This remark applies more especially to pleurodynia. The tenderness in both affections varies, being sometimes slight and sometimes exquisitely acute.

Of the two affections, pleurodynia is much the less frequent. Before the diagnostic criterion of intercostal neuralgia had been pointed out by Bassereau and Valleix, cases of this affection were doubtless often considered as rheumatic, and hence cases of the neuralgic affections have apparently increased of late at the expense of pleurodynia. Intercostal neuralgia is of frequent occurrence. Cases are often met with both in private practice and among patients treated at hospitals and dispensaries, but more especially the latter. The poorer classes are more liable to it than those in comfortable circumstances. It occurs oftener among females than males. Persons affected are frequently anæmic. It is liable to be developed during the progress of pulmonary phthisis. It occurs especially as a sequel of intermittent fever.

The degree of suffering from these affections varies much in different cases. They are sometimes so slight as merely to occasion annoyance, but in some cases the pain is sufficiently severe to shorten the inspirations, thus rendering the respirations frequent, as in acute pleuritis, and occasioning great distress. In the neuralgic affection exacerbations of pain are frequently experienced. They vary greatly in different cases, as regards duration, occurring sometimes as transient affections, but in some cases persisting for a long period. Pain and soreness in the chest are sometimes assumed by malingerers, but a ready proof of the reality of the affection is the diagnostic test—namely,

The mucous membrane of the bronchi is always inflamed in phthisis. Ulcers, usually of tuberculous origin, are frequent. The various forms of *peribronchitis*, called tuberculous, caseous, purulent, or fibrous, are sufficiently explained by these terms. Some form of *peribronchitis* is a constant attendant of phthisis.

Inflammation of the interstitial tissue of the lung, leading to the formation of new connective tissue, is called *chronic interstitial pneumonitis*, and is present in some degree in all cases of chronic pulmonary phthisis. The new tissue encroaches upon the pulmonary parenchyma, causing the obliteration of air-cells and shrinkage of the affected portion of the lung. New fibrous tissue may be formed, as previously stated, directly from tubercle-nodules, from disused tubercle-tissue, or as a result of chronic interstitial inflammation. Fibroid phthisis, which is characterized by an excessive formation of fibrous tissue and retraction of the lung, presents sufficient clinical peculiarities to demand special consideration, which will be given in the next article.

Pulmonary phthisis is always accompanied by *pleuritis*, usually of the dry form. The *pleuritis* leads to the formation of vascular adhesions, which are, as a rule, most extensive and firmest at the apices of the lungs.

It is customary to find around tubercle-nodules and foci of cheesy pneumonia the air-cells filled with the ordinary products of inflammation. Patches of ordinary catarrhal or of fibrinous pneumonia may also occur in parts of the lung which do not contain tubercles or caseous masses. Pneumonia of this form does not undergo cheesy degeneration unless the affected part of the lung be invaded by tubercle bacilli.

Of *non-inflammatory changes* deserving mention, there are pigmentation with coal-particles and with melanin, particularly in newly-formed fibrous tissue; atelectasis; compensatory emphysema; congestion and localized and general œdema.

As the expectoration contains tubercle bacilli, it is common to find tuberculous lesions in the respiratory tract above the lungs, especially in the larger bronchi, the trachea, and the larynx. These lesions are usually in the form of tuberculous ulcers, and are in nearly all cases secondary to the pulmonary affection.

By swallowing sputum which contains the tubercle bacilli the tuberculous virus may gain access to the intestinal tract and cause tuberculous ulceration, which is found most frequently in the lower part of the ileum. From the intestine the bacilli may be readily conveyed to the peritoneum, the mesenteric glands, and the liver, which in many cases of phthisis are found to contain miliary tubercles.

The number of bacilli present in different cases of phthisis is subject to considerable variation. In some cases they are abundant and occur in dense masses; and in other cases they are scanty and found only after long search. The bacilli are present in the bodies of cells, particularly of epithelioid and of giant-cells, and also free between the cells. They are always present in the beginning of tuberculous processes, and also when the tuberculous formation is in rapid progress. The bacilli are usually few or entirely absent in cheesy matter, but there are exceptions to this rule. When the cheesy substance is in communication with the atmosphere, as in the walls of phthisical cavities, the bacilli are generally abundant. Cheesy matter, even if bacilli are absent, usually contains the spores of the bacilli, as is evident from the possibility of producing artificial tuberculosis by the inoculation of cheesy substance which is free from bacilli. We are at present unable to demonstrate by coloring agents the free spores of tubercle bacilli.

The most important biological properties of the bacilli of tuberculosis are the development of spores, the slow growth of the bacilli, and the fact that

strongylus gigas, as well as in the bases of syphilitic and cancerous ulcers. It is, however, exceptional to find it under such circumstances, whereas its presence in association with the bacillus tuberculosis is the rule. A brief description of the anatomical characters of tubercle is therefore appropriate.

Macroscopically, tubercle appears under one of two forms: (1) As a small nodule or "granulation," varying in diameter from 0.5 to 2 or 3 millimetres, which is transparent in its early stages, but later becomes opaque or yellowish in the centre. These granulations attain their most typical development in the serous membranes, where they are often surrounded by an area of congestion; they are commonly known as miliary tubercles. (2) As larger nodules, which may attain the size of a pea or a walnut, or may infiltrate the affected organ to a great extent, forming what is commonly called a caseous mass. In either case the tubercle is made up of aggregations of "elementary tubercles" which only become visible with the aid of the microscope.

The ideal elementary tubercle is composed of three zones. In its centre is a giant-cell—that is, a mass of protoplasm containing in its peripheral portion from twenty to thirty nuclei arranged in a circular manner; next comes a zone of epithelioid cells; and outermost of all a layer or zone of embryonic cells. These various elements are united by a network of connective tissue resembling the adenoid tissue of lymph-glands and continuous with processes which originate in the central giant-cell.

The most marked anatomical characteristic of tubercle is that it is non-vascular, the vessels originally in its embrace becoming obliterated at an early stage of the neoplasm by coagula of a granular character. The subsequent degeneration of a tubercular infiltration is due to this absence of vascularity.

The specific bacilli are most abundant in the central giant-cell. In the epithelioid zone they may be also found in the interior of the cells and in the interstices between them. The central bacilli—those contained in the giant-cell—do not behave in a uniform manner toward the usual stains. Some of them stain vividly, others feebly or not at all, and the latter are believed to be dead. It is supposed, therefore, that the giant-cells act the part of "phagocytes," and that the presence of the bacilli in their interior, instead of being accidental, is the result of their function—phagocytosis.

The elementary tubercle above described is often called, especially by the French, a tubercular "follicle," probably from its fancied resemblance to the Malpighian bodies or "follicles" of the spleen. In fact, Virchow formerly classified tubercle among the lymphomata, on account of its resemblance to lymphatic structures.

The foregoing brief description of the minute anatomy of tubercle is essential to an understanding of the protean gross appearances of tuberculosis in the various tissues and organs of the body.

The progress of tubercle is either toward caseous degeneration or fibroid metamorphosis. The former begins with cellular changes. The nuclei both of the giant and epithelioid cells disappear, and the cell-bodies become fused into a semi-transparent substance closely resembling the degeneration known as amyloid or lardaceous. It does not, however, give the reactions of the latter.

The semi-transparent mass soon becomes opaque, making it impossible to distinguish any trace of cellular structure, and finally the bacilli themselves disappear. For a long time this "caseous" change was believed to be characteristic of tuberculosis, but this is now known to be a mistake. Caseous degeneration does not always take place even in cases of extensive tubercular infiltration, and, on the other hand, it may occur in the products of non-tuber-

cular inflammation, especially when these are of syphilitic origin. It is erroneous, therefore, to regard this change as due to deficient blood-supply, for in syphilitic caseous foci the vessels continue to be pervious. The caseous metamorphosis is most probably due to the action of soluble products of the bacilli.

A caseous focus may become indurated or softened. In the former event it becomes infiltrated with the salts of lime, which appear first in the centre of the mass and gradually extend to the periphery until it is converted into a calcareous mass. It may then become encapsulated and persist indefinitely in the lung as an innocuous foreign body.

Sometimes the process stops short of complete calcification, the caseous focus becoming converted into a pultaceous or mortar-like mass surrounded by a capsule. Finally, the cheesy deposit may be completely liquefied and absorbed, its site being indicated post-mortem by a puckered cicatrix. Softening is most likely to occur when the tubercular mass is situated near the surface. The puriform fluid is possessed of corrosive properties, and makes its way in the direction of least resistance. This tendency to seek an outlet is constantly seen in cases of pulmonary tuberculosis, and doubtless because the methods of exit from the lung are more numerous than in other organs of the body. A bronchus is perforated, the softened products are expectorated, and there remains behind a cavity, which usually has a tendency to extend by the progressive destruction of its walls. Neighboring cavities may unite so as to form *vomicæ* of most irregular contour. Their walls are usually composed of caseous material which may be scraped away with the knife. In the most favorable cases there is formed upon the inner surface of the cavity a kind of granulation tissue which terminates in the formation of a smooth serous-like membrane, and although the cavity still remains patulous, it has no tendency toward further extension, and may be regarded as healed.

In the course of this cavity-formation the blood-vessels oppose a remarkable resistance to the destructive process. In the lung, vessels of considerable size may be seen traversing a vomica, but, although externally they may appear unaltered, on section their walls are seen to be thickened and their lumen obliterated. The vessels which ramify on the walls of the cavity remain, as a rule, patulous, and they frequently undergo aneurismal dilatation. The occurrence of aneurisms in this situation was first discovered by Rasmussen of Copenhagen, who attributed their origin to the unsupported state of the vessels. They are generally of small size, and can only be detected by careful dissection. Their rupture is probably the commonest cause of suddenly fatal hæmoptysis.

Instead of caseating, a tubercular focus may undergo a sclerotic or fibroid change, its cellular elements becoming converted into fibrous tissue. This metamorphosis is most apt to occur in slowly progressive cases, and especially in persons advanced in life in whom there coexists a sclerotic condition of the arteries. The fibroid change is most often observed in tuberculosis of the peritoneum; in fact, in this situation the natural tendency of the disease is toward cure by the excessive development of connective tissue which encloses and strangles the bacilli in its meshes.

From the foregoing remarks it is plain that in tuberculosis there may frequently be observed an effort of nature toward the cure of the disease, and this effort is often attended with success, as is manifested by the evidences of healed tuberculosis in the lungs of persons dying of all kinds of diseases.—H.]

In acute miliary tuberculosis, which will be described subsequently, miliary tubercles are found scattered throughout both lungs. In these cases the

tubercle bacilli are conveyed to the lungs by the blood-current. In many cases of phthisis an eruption of miliary tubercles is found for a variable distance around a cheesy focus or an old tuberculous nodule. Here the tubercle bacilli are conveyed by the lymphatics. The usual mode of access of the tubercle bacilli to the lungs is by the respiratory passages. In this mode of access the first effect of the bacilli is to cause the production of tuberculous nodules in the air-cells, the alveolar passages, and the terminal bronchi, where the bacilli lodge.

The production of *cheesy pneumonia* is an effect of the tubercle bacilli not less important than the production of tubercles. This form of pneumonia has been called also tuberculous pneumonia, desquamative pneumonia, and infiltrated tubercle. The air-cells are filled with epithelioid cells, lymphoid cells, usually but not always fibrin, and sometimes red blood-corpuscles. The alveolar walls are frequently infiltrated with cells. The solidified portions of lung are at first moist and reddish-gray in color; later they become gray and dry, and finally cheesy. In rare instances caseous pneumonia involves a whole lobe; usually it is lobular in distribution. The smaller bronchi are generally involved. They contain caseous plugs and have thickened caseous walls (caseous peribronchitis).

Inasmuch as tubercles are often formed partly or wholly by accumulations of cells in the alveoli, it is manifestly difficult, and after cheesy degeneration has ensued often impossible, to draw any sharp line of distinction between tubercles and foci of cheesy pneumonia. This distinction, however, is less important than was formerly supposed, inasmuch as the tubercle bacilli are present in the caseous pneumonia as well as in the tubercles, and are the cause of both processes.

In most cases of rapid or the so-called galloping *phthisis* (*phthisis florida*) more or less extensive patches of caseous pneumonia form the greater part of the lesions. Tubercles, however, are usually present at the same time. When a large number of tubercle bacilli gain access to the lung through the respiratory passages, as often happens in children by the bursting of a caseous bronchial gland into a bronchus, then caseous pneumonia rapidly develops, and involves a large portion of the lung at once. A similar result may follow when a cheesy focus or a cavity in any part of the lung opens into a bronchus, and thus allows a large number of bacilli to be inspired into other bronchial tubes.

Changes in the blood-vessels of the lung are of importance in the pathology of phthisis. Tubercles are non-vascular structures, as has already been explained. The pre-existing vessels, where the tubercles develop, become obliterated, partly by thrombosis and partly by an accumulation of epithelioid and lymphoid cells in their lumen. A similar process of obliteration occurs when tuberculous pneumonia undergoes cheesy degeneration. The blood-supply of the lung is furthermore greatly impeded by an inflammatory thickening of the inner coat of many of the small and medium-sized arteries, by which process the lumen of the vessel is gradually encroached upon, and may be finally obliterated. This process is called *endarteritis obliterans*. Endophlebitis obliterans is also frequent. Tubercles may be found in all of the coats of the blood-vessels. Tubercles, and especially cheesy masses which invade the inner coat of the pulmonary veins, are of grave significance, for in this way the tubercle bacilli may enter the blood-current and be transported to all parts of the body, causing a general miliary tuberculosis. The obstructions to the blood-current which have been described undoubtedly favor the cheesy degeneration of tubercle and of pneumonic products, but probably to a much greater extent the cheesy degeneration is a direct effect of the action of the tubercle bacilli.

The mucous membrane of the bronchi is always inflamed in phthisis. Ulcers, usually of tuberculous origin, are frequent. The various forms of *peribronchitis*, called tuberculous, caseous, purulent, or fibrous, are sufficiently explained by these terms. Some form of peribronchitis is a constant attendant of phthisis.

Inflammation of the interstitial tissue of the lung, leading to the formation of new connective tissue, is called *chronic interstitial pneumonitis*, and is present in some degree in all cases of chronic pulmonary phthisis. The new tissue encroaches upon the pulmonary parenchyma, causing the obliteration of air-cells and shrinkage of the affected portion of the lung. New fibrous tissue may be formed, as previously stated, directly from tubercle-nodules, from diffuse tubercle-tissue, or as a result of chronic interstitial inflammation. Fibroid phthisis, which is characterized by an excessive formation of fibrous tissue and retraction of the lung, presents sufficient clinical peculiarities to demand special consideration, which will be given in the next article.

Pulmonary phthisis is always accompanied by *pleuritis*, usually of the dry form. The pleuritis leads to the formation of vascular adhesions, which are, as a rule, most extensive and firmest at the apices of the lungs.

It is customary to find around tubercle-nodules and foci of cheesy pneumonia the air-cells filled with the ordinary products of inflammation. Patches of ordinary catarrhal or of fibrinous pneumonia may also occur in parts of the lung which do not contain tubercles or caseous masses. Pneumonia of this form does not undergo cheesy degeneration unless the affected part of the lung be invaded by tubercle bacilli.

Of *non-inflammatory changes* deserving mention, there are pigmentation with coal-particles and with melanin, particularly in newly-formed fibrous tissue; atelectasis; compensatory emphysema; congestion and localized and general œdema.

As the expectoration contains tubercle bacilli, it is common to find tuberculous lesions in the respiratory tract above the lungs, especially in the larger bronchi, the trachea, and the larynx. These lesions are usually in the form of tuberculous ulcers, and are in nearly all cases secondary to the pulmonary affection.

By swallowing sputum which contains the tubercle bacilli the tuberculous virus may gain access to the intestinal tract and cause tuberculous ulceration, which is found most frequently in the lower part of the ileum. From the intestine the bacilli may be readily conveyed to the peritoneum, the mesenteric glands, and the liver, which in many cases of phthisis are found to contain miliary tubercles.

The number of bacilli present in different cases of phthisis is subject to considerable variation. In some cases they are abundant and occur in dense masses; and in other cases they are scanty and found only after long search. The bacilli are present in the bodies of cells, particularly of epithelioid and of giant-cells, and also free between the cells. They are always present in the beginning of tuberculous processes, and also when the tuberculous formation is in rapid progress. The bacilli are usually few or entirely absent in cheesy matter, but there are exceptions to this rule. When the cheesy substance is in communication with the atmosphere, as in the walls of phthisical cavities, the bacilli are generally abundant. Cheesy matter, even if bacilli are absent, usually contains the spores of the bacilli, as is evident from the possibility of producing artificial tuberculosis by the inoculation of cheesy substance which is free from bacilli. We are at present unable to demonstrate by coloring agents the free spores of tubercle bacilli.

The most important biological properties of the bacilli of tuberculosis are the development of spores, the slow growth of the bacilli, and the fact that

near the apex, the different gradations of the first stage may be represented in other parts. The disease is to be considered as having advanced to the second stage when it has led to the formation of a cavity or of cavities of sufficient size to give rise to certain distinctive signs and symptoms. The symptoms of the first stage continue into the second, in most cases being increased and modified by the existence of cavities.

The cough in the second stage usually becomes more prominent. It may be less irritable, and more exclusively for expectoration. It is troublesome and difficult in proportion as the contents of the cavities are not easily evacuated, owing to their size, want of free communication with the bronchial tubes, etc. The expectoration consists of liquefied phthical products, matter furnished by the lining membrane of the cavities, and secretion from the bronchial mucous membrane. The quantity of expectoration is very variable, amounting in some cases to only a few ounces, and in other cases to a pint or more daily.

The appearances of the expectoration vary. It is oftenest muco-purulent, with more or less predominance of the characters of pus. In proportion as it is purulent the sputa do not remain distinct, but run together to form a homogeneous mass. Sometimes a collection of the liquid expectorated presents a thick, opaque appearance, not unlike that of pea-soup or gruel. The sputa are sometimes solid, remaining distinct, and in falling upon the bottom of a vessel assume a flat, round appearance like that of a coin, and hence are called *nummular sputa*. The sputa occasionally present yellow *striae*, which consist apparently of pus. The edges of the sputa are sometimes ragged; another appearance is that of small particles, resembling boiled rice, contained in the matter expectorated. It is very rare for a semi-softened, cheesy, morbid product to be expectorated; but in a case under my observation several masses of this description were raised, evidently due to an unusually large ulcerated orifice being established between a collection of tuberculous products and a bronchial tube of considerable size. In this case the signs of a cavity were developed directly after the expectoration of a large amount of matter which contained the partially softened masses. A sudden expectoration of matter in considerable quantity, presenting a purulent or pyoid appearance, denotes the opening by ulceration of a so-called tuberculous abscess. Not infrequently this occurs repeatedly during the progress of the disease, but in many cases the ulcerated opening is at first small, and the liquefied matter escapes gradually into the bronchial tubes. The constituents, as shown by the microscope, are pus-corpuscles, epithelium, fatty granules, blood-discs, the yellow elastic fibre, and tubercle bacilli.

The quantity of matter expectorated is, in general, in proportion to the number and size of the cavities. It is usually more abundant in the morning than at any other time, owing to its having accumulated during sleep. Toward the close of life the act of expectoration becomes difficult on account of muscular feebleness, and the consequent accumulation in the air-passages not infrequently hastens death. Occasionally the matter expectorated and the breath of the patient emit considerable fetor, due to putrefaction of the contents of cavities.

Hæmoptysis occurs less frequently in the second than in the first stage; and occurring in the second stage it may be due to the rupture of the bands of pulmonary tissue which so often traverse tuberculous cavities, these bands sometimes containing vessels of sufficient size to furnish an abundant hemorrhage, or more frequently to rupture of the minute aneurisms in the walls of the cavities, to which reference has been made in the account of the anatomical characters. Sometimes the loss of blood in this way is sufficient to

destroy life, but such instances are rare. The hemorrhage, however, may contribute to a fatal result.

Hoarseness or huskiness, and sometimes extinction of the voice, denote laryngitis, which may be developed in the first as well as in the second stage. Its occurrence is presumptive proof of pulmonary phthisis, the latter, as a rule, existing prior to the laryngitis.

Lancinating pains incident to circumscribed pleuritis recur in the second as well as in the first stage from time to time. Occasionally, both in the first and second stage, the pleuritis becomes general and occasions more or less liquid effusion. So far as my observations go, they confirm the statement by Louis, that double pleuritis with effusion denotes the pre-existence of tubercle. Acute pain, suddenly developed, with embarrassed breathing, acceleration of pulse, and prostration, point to perforation of the lung, and the signs of pleurisy with pneumothorax are to be sought for.

The pulse, as a rule, is more accelerated in the second than in the first stage. Febrile exacerbations are oftener present and more marked, with burning of the soles and palms. The night-perspirations are often copious, causing debility and great discomfort.

The appetite and digestion are more or less impaired, cases differing greatly as regards the symptoms connected with the ingestion of food. Diarrhoea is more frequently present, and is a more prominent symptom in the second stage, being connected often with intestinal ulcerations. If profuse and persisting, it has been distinguished as *colliquative diarrhoea*. Colliquative diarrhoea occurs at an advanced period of the disease, although tuberculosis of the intestines does not exist. With the progress of the disease the body progressively diminishes in weight, and the patient is often reduced to an extreme degree of emaciation. The strength varies greatly in this stage. The patient may be confined to the bed for a greater or less period before death, but not infrequently strength is preserved sufficiently for him to be up much of the time, and even to go out of doors, within a few days or even a few hours of death.

Bulbous enlargement of the ends of the fingers, with incurvation of the nails, forming what are called *clubbed fingers*, is occasionally observed. This peculiar appearance is characteristic of phthisis, but it is not pathognomonic. It may be strikingly marked in connection with organic disease of the heart without phthisis. It occurs in cases of fibroid phthisis oftener than in the form of the disease under present consideration. The toes may present a similar appearance, but in a less marked degree. These appearances occur only in cases in which the disease has existed for a considerable period. Of 1776 cases analyzed by Pollock, the fingers were more or less clubbed in 654, being a fraction under 27 per cent.

The mental condition in the second stage is frequently not less characteristic than in the first. The expectation of improvement, prolonged life, or even recovery, amounts in some cases to an insane delusion. Patients are sometimes occupied in forming plans for the future when it is obvious to any observer that they are on the verge of the grave. They may insist to the last that there is no danger. Over and over again in the hospital wards I have been asked by patients reduced almost to skeletons, and too feeble to sit up for a moment, if there was any danger or if they would recover. But whenever patients affected with this disease are satisfied that there is little or no hope of recovery, they generally become quickly and completely resigned.

Edema of the feet and ankles is a symptom of the second stage, denoting notable failure of the circulation. For a time this may occur only after sitting or standing, disappearing after the recumbent posture has been maintained for

represented by the pulse, holds an important place. During the first stage more or less acceleration of the pulse is the rule, and this acceleration, although not great, is an important diagnostic symptom. The acceleration differs much in different cases. In general, it is in proportion to the activity of the disease. If the pulse be frequent the disease is likely to be rapidly progressive.

The temperature is more or less raised in proportion as the disease is progressive. The thermometer thus aids in the diagnosis of the disease, and if the diagnosis be not doubtful it affords evidence of the disease being progressive or otherwise. When it is a question as to the diagnosis, increase of temperature is evidence for, and absence of any increase is evidence against, the existence of the disease. In well-marked cases the increase is a measure of the activity of the disease, whereas a normal temperature denotes that the disease is non-progressive.

Daily exacerbations of fever may occur in the first stage. Toward evening the acceleration of the pulse is increased, with increased heat of skin, and sometimes a marked sensation of burning in the soles and palms; the cheeks may present a bright circumscribed flush, and after some hours the exacerbation goes off with perspiration. The exacerbation is sometimes preceded by a chill. Chills also occur without being followed by notable febrile movement. They may be pronounced and accompanied by rigor, or they are slight and transient, consisting in some cases of occasional shiverings or a sensation as if water were trickling down the back. Well-marked chills, followed by increased heat and perspiration, may occur with such regularity that the patient is supposed to have intermittent fever, and under these circumstances, if the pulmonary symptoms be slight, the affection of the lungs may be for some time overlooked. I suppose there are few physicians of much experience in situations where they are liable to meet with intermittent fever who cannot recall cases in which this error of diagnosis has been made. Fever of limited duration may be due to an intercurrent circumscribed pneumonitis.

As regards appetite and digestion, there is much diversity in different cases. In general, the desire for food and the ability to digest it are diminished. In some cases there is almost entire loss of appetite, and even a repugnance to food. This is an unfavorable feature of the disease. Disorder of digestion is sometimes so prominent as to appear to be the chief malady. The physician should be on his guard against considering the cough in such cases as merely dyspeptic or sympathetic. Antipathy to fat is by no means constant; some patients take fatty articles of food freely without repugnance and with relish; and on the other hand not a few patients who are not phthisical have an antipathy to fat.

Diarrhœa occurs in the first stage in a certain proportion of cases. It may exist with and without a tuberculous affection of the intestinal canal, usually seated in the small intestine. Persisting or frequently recurring diarrhœa, accompanied by cough, be the latter never so slight, should excite suspicion of pulmonary phthisis, and the existence of this affection being ascertained, a tuberculous affection of the intestinal canal as a secondary affection is probable. This affection results from swallowing the expectoration. Diarrhœa having this significance is an unfavorable symptom, diminishing the prospect of improvement. The seat of the affection is usually the Peyerian and solitary glands. It leads to ulcerations differing from those which are characteristic of typhoid fever in a tendency to extend in a transverse direction and to occupy only portions of the elliptical patches; also in having hardened and raised margins. Tuberculous ulcerations are sometimes found in the large as well as in the small intestine, and they may be confined to the former. The ulcerations may lead to circumscribed peritonitis, and

the peritoneal inflammation sometimes becomes general. Perforation of the intestine occasionally takes place, giving rise to general peritonitis, provided the peritoneal surfaces over the ulcerated space within which the perforation occurs have not become adherent from previous circumscribed inflammation. Intestinal hemorrhage sometimes takes place, and I have known it to prove the immediate cause of death.

Impaired nutrition, denoted by diminished weight, is frequently one of the earliest symptoms. As a rule, reduction in weight continues so long as the disease is progressive; on the other hand, the disease may be considered as non-progressive if the patient be not losing weight, and still more if he be gaining in flesh.

[It is commonly assumed that anæmia is a symptom of the early stage of phthisis, and that the deficiency in blood-corpuscles and hæmoglobin progressively increases as the disease advances. This is far from being the case. I have often examined the blood in cases of far-advanced pulmonary phthisis without finding the red corpuscles reduced below 75 per cent. of the normal number. On February 23, 1888, I examined the blood of a colored woman in the last stages of tuberculosis pulmonum (she died on March 11, 1888), and found 3,660,000 red corpuscles per cubic m. (73.2 per cent.) and 50 per cent of hæmoglobin. I was pleased to find my observations confirmed by Dr. O. Oppenheimer,¹ who examined the blood in a considerable number of cases of well-pronounced phthisis and found it normal in all respects. The researches of Laache of Christiania yielded similar results.—H.]

The muscular strength progressively diminishes if the disease be progressive, but here there is much variation in different cases. Patients are rarely compelled to keep the bed in the first stage, and they are generally able to be out of doors. Deficiency of breath in some cases precludes an amount of active exercise or labor for which muscular strength is sufficiently retained.

Suppression of the menses is a symptom significant of the progress of the disease; the menstrual discharge diminishes in quantity, and in the course of the disease ceases. Patients often attribute importance to the suppression as a cause of their other ailments. It is, however, an event incidental to the disease, and does not claim special treatment. Facts do not show that suppression of the menses from other causes exerts an influence in the development of phthisis.

This disease does not tend directly to impair the intellectual faculties. The intellect frequently remains bright and active notwithstanding the progress of the disease. The feelings are usually cheerful and buoyant. Patients are hopeful respecting their condition; they depreciate their symptoms and are reluctant to admit that they have a serious malady. This state of mind sometimes amounts to an infatuation which renders it difficult to obtain from the patient a fair account of the symptoms, and it is necessary for the physician to rely chiefly on the statements of others and his own observations. To such an extent is the absence of anxiety characteristic of the disease that an opposite frame of mind militates somewhat against the existence of phthisis. Patients are readily persuaded that they are improving, and hence they fall an easy prey to quacks. They sometimes dislike to be told the truth, and take offence at an intimation that they are consumptive.

Proceeding to notice the points in the clinical history which distinguish the second stage, it is to be borne in mind that it is not easy, nor is it practically important, to draw an exact line of demarcation between the two stages. While the local affection has advanced to the second stage in one part, usually

¹ *Deutsche med. Wochenschrift*, Oct. 24, 1889.

near the apex, the different gradations of the first stage may be represented in other parts. The disease is to be considered as having advanced to the second stage when it has led to the formation of a cavity or of cavities of sufficient size to give rise to certain distinctive signs and symptoms. The symptoms of the first stage continue into the second, in most cases being increased and modified by the existence of cavities.

The cough in the second stage usually becomes more prominent. It may be less irritable, and more exclusively for expectoration. It is troublesome and difficult in proportion as the contents of the cavities are not easily evacuated, owing to their size, want of free communication with the bronchial tubes, etc. The expectoration consists of liquefied phthysical products, matter furnished by the lining membrane of the cavities, and secretion from the bronchial mucous membrane. The quantity of expectoration is very variable, amounting in some cases to only a few ounces, and in other cases to a pint or more daily.

The appearances of the expectoration vary. It is oftenest muco-purulent, with more or less predominance of the characters of pus. In proportion as it is purulent the sputa do not remain distinct, but run together to form a homogeneous mass. Sometimes a collection of the liquid expectorated presents a thick, opaque appearance, not unlike that of pea-soup or gruel. The sputa are sometimes solid, remaining distinct, and in falling upon the bottom of a vessel assume a flat, round appearance like that of a coin, and hence are called *nummular sputa*. The sputa occasionally present yellow *striae*, which consist apparently of pus. The edges of the sputa are sometimes ragged; another appearance is that of small particles, resembling boiled rice, contained in the matter expectorated. It is very rare for a semi-softened, cheesy, morbid product to be expectorated; but in a case under my observation several masses of this description were raised, evidently due to an unusually large ulcerated orifice being established between a collection of tuberculous products and a bronchial tube of considerable size. In this case the signs of a cavity were developed directly after the expectoration of a large amount of matter which contained the partially softened masses. A sudden expectoration of matter in considerable quantity, presenting a purulent or pyoid appearance, denotes the opening by ulceration of a so-called tuberculous abscess. Not infrequently this occurs repeatedly during the progress of the disease, but in many cases the ulcerated opening is at first small, and the liquefied matter escapes gradually into the bronchial tubes. The constituents, as shown by the microscope, are pus-corpuscles, epithelium, fatty granules, blood-discs, the yellow elastic fibre, and tubercle bacilli.

The quantity of matter expectorated is, in general, in proportion to the number and size of the cavities. It is usually more abundant in the morning than at any other time, owing to its having accumulated during sleep. Toward the close of life the act of expectoration becomes difficult on account of muscular feebleness, and the consequent accumulation in the air-passages not infrequently hastens death. Occasionally the matter expectorated and the breath of the patient emit considerable fetor, due to putrefaction of the contents of cavities.

Hæmoptysis occurs less frequently in the second than in the first stage; and occurring in the second stage it may be due to the rupture of the bands of pulmonary tissue which so often traverse tuberculous cavities, these bands sometimes containing vessels of sufficient size to furnish an abundant hemorrhage, or more frequently to rupture of the minute aneurisms in the walls of the cavities, to which reference has been made in the account of the anatomical characters. Sometimes the loss of blood in this way is sufficient to

destroy life, but such instances are rare. The hemorrhage, however, may contribute to a fatal result.

Hoarseness or huskiness, and sometimes extinction of the voice, denote laryngitis, which may be developed in the first as well as in the second stage. Its occurrence is presumptive proof of pulmonary phthisis, the latter, as a rule, existing prior to the laryngitis.

Lancinating pains incident to circumscribed pleuritis recur in the second as well as in the first stage from time to time. Occasionally, both in the first and second stage, the pleuritis becomes general and occasions more or less liquid effusion. So far as my observations go, they confirm the statement by Louis, that double pleuritis with effusion denotes the pre-existence of tubercle. Acute pain, suddenly developed, with embarrassed breathing, acceleration of pulse, and prostration, point to perforation of the lung, and the signs of pleurisy with pneumothorax are to be sought for.

The pulse, as a rule, is more accelerated in the second than in the first stage. Febrile exacerbations are oftener present and more marked, with burning of the soles and palms. The night-perspirations are often copious, causing debility and great discomfort.

The appetite and digestion are more or less impaired, cases differing greatly as regards the symptoms connected with the ingestion of food. Diarrhœa is more frequently present, and is a more prominent symptom in the second stage, being connected often with intestinal ulcerations. If profuse and persisting, it has been distinguished as *colliquative diarrhœa*. Colliquative diarrhœa occurs at an advanced period of the disease, although tuberculosis of the intestines does not exist. With the progress of the disease the body progressively diminishes in weight, and the patient is often reduced to an extreme degree of emaciation. The strength varies greatly in this stage. The patient may be confined to the bed for a greater or less period before death, but not infrequently strength is preserved sufficiently for him to be up much of the time, and even to go out of doors, within a few days or even a few hours of death.

Bulbous enlargement of the ends of the fingers, with incurvation of the nails, forming what are called *clubbed fingers*, is occasionally observed. This peculiar appearance is characteristic of phthisis, but it is not pathognomonic. It may be strikingly marked in connection with organic disease of the heart without phthisis. It occurs in cases of fibroid phthisis oftener than in the form of the disease under present consideration. The toes may present a similar appearance, but in a less marked degree. These appearances occur only in cases in which the disease has existed for a considerable period. Of 1776 cases analyzed by Pollock, the fingers were more or less clubbed in 654, being a fraction under 27 per cent.

The mental condition in the second stage is frequently not less characteristic than in the first. The expectation of improvement, prolonged life, or even recovery, amounts in some cases to an insane delusion. Patients are sometimes occupied in forming plans for the future when it is obvious to any observer that they are on the verge of the grave. They may insist to the last that there is no danger. Over and over again in the hospital wards I have been asked by patients reduced almost to skeletons, and too feeble to sit up for a moment, if there was any danger or if they would recover. But whenever patients affected with this disease are satisfied that there is little or no hope of recovery, they generally become quickly and completely resigned.

Edema of the feet and ankles is a symptom of the second stage, denoting notable failure of the circulation. For a time this may occur only after sitting or standing, disappearing after the recumbent posture has been maintained for

some hours; but at length it is permanent, and may increase and extend over the whole of the lower extremities, rendering them unwieldy. When the œdema becomes thus marked, extensive, and permanent, thrombosis of the iliac or femoral veins is to be suspected—an event which is liable to occur in this disease. Coagulation in the vein on one side will account for the œdema in some cases in which it is either limited to or is much greater in one of the lower limbs. If the œdema be diffused over the body, constituting anasarca, coexisting disease of the kidneys is to be inferred.

The clinical history is affected in no small degree by complications and coexisting affections. The occurrence of tuberculous disease of the intestines, tuberculous laryngitis, pleuritis with pneumothorax, and disease of the kidneys has been already referred to. Chronic peritonitis is an occasional complication. The researches of Louis demonstrated that chronic peritonitis, not traumatic, is almost invariably dependent on tuberculosis in this situation, and hence, from the existence of the peritoneal affection, pulmonary phthisis may be inferred. Acute peritonitis from perforation is sometimes incident to the tuberculous affection within the intestinal canal. Meningitis, usually tuberculous, occurs as a rare concomitant in the adult, but is not infrequent in early life. This coexisting affection accounts for the development of delirium and coma in certain cases. Perineal abscess, leading to fistula, is another complication occurring in a certain proportion of cases, proceeding, as microscopical examinations have shown, from tubercle in this situation. Clinical observation appears to show that, as a rule, when this complication occurs the amount of tubercle in the lungs is small or moderate and the progress of the pulmonary affection is slow. An accumulation of fat within the liver-cells is a morbid condition observed in a considerable proportion of cases, occurring oftener in women than in men. Authors of works on the diseases of the skin have noted the occasional occurrence of tinea versicolor in phthisical patients.

The duration of this disease is extremely variable. In the vast majority of cases it is essentially a chronic affection, but sometimes it runs a rapid course, passing through its changes and destroying life in a few weeks. The disease in such cases has been known as "galloping consumption," or phthisis florida. It is different from that known as *acute miliary tuberculosis*, which will be noticed under a distinct heading. Distributing fatal cases into groups according to the duration of the disease, exclusive of the rapid cases just referred to, one group will consist of cases in which the disease continues from three to six months; in another group death takes place between six months and a year; in a third group the career extends from one to two years; and in another group the fatal termination is held in abeyance for many years.

Limiting attention to the cases in which sooner or later the disease proves fatal, its march is extremely irregular. It is not uncommon for little or no progress to be apparent for several successive weeks, months, or even years and then the disease to advance with more or less rapidity. Distinct developments occurring at successive periods are frequently points of departure for the onward march of the disease; but cases differ much as regards the local destruction and the rapidity with which softening, ulceration, and the formation of cavities take place. (Further remarks on the march of the disease will be offered under the head of Prognosis.)

PATHOLOGICAL CHARACTER.—In a practical point of view pulmonary phthisis involves the co-operation of two pathological factors. One of these is the bacillus tuberculosis. This is an essential factor. The colonization of this micro-organism within the lungs is the primary step in the produc-

tion of pulmonary phthisis. Certain local conditions favorable for the multiplication of the parasite are not less essential than the presence of the latter. The nature of those local conditions which form the soil suited for the cultivation of the parasite is unknown. Certain conclusions deduced from clinical observations will be noted in connection with the causation of the disease. These unknown conditions constitute a predisposition to this disease. This term, "predisposition," in its application to pulmonary phthisis, designates what has hitherto been expressed by the terms tuberculous constitution and diathesis.

CAUSATION.—The causes of pulmonary phthisis relate, first, to the specific micro-organism, the bacillus tuberculosis; and second, to the conditions which constitute a tuberculous predisposition or diathesis. The disease is never produced without the parasite, but the efficiency of this agent depends on the predisposition or diathesis. The latter alone is incapable of producing the disease. If the introduction of the parasite into the air-passages could be prevented, the disease would not be produced, no matter how strong the predisposition; and, on the other hand, if the predisposition be wanting the disease will not be produced, no matter how great the exposure to the specific cause. Absolute prevention of exposure to the specific cause is only possible in situations in which tuberculous disease does not exist, either in man or lower animals. The exposure is greater, other things being equal, the greater the prevalence of the disease, and in proportion as circumstances favor proximity to patients affected with it. When it is considered that about one-seventh of all human beings die of phthisis, it is not difficult to account for the wide distribution of the tuberculous virus. The fact that protection against the introduction of the parasite is impossible in most places renders the causes of the tuberculous predisposition especially important.

The bacillus tuberculosis is not capable of multiplication outside of the animal body under the ordinary conditions of nature, and hence pulmonary phthisis is not only an infectious but a contagious disease. The parasite is the contagium. The contagiousness of this disease—which has long been a moot question—is not easily established by clinical evidence, the instances being so many in which circumstances favorable to communicability are present without its being communicated. Moreover, the doctrine of chances explains the occurrence of a disease so prevalent as this in a certain number of those who are brought more or less intimately into close proximity to phthisical patients. That the tubercle bacillus is the living contagium of tuberculosis the experiments of Koch and others have established demonstratively by the inoculation of certain of the lower animals with pure cultures of this micro-organism. The disease is never produced without the agency of this contagium; but many persons are exposed thereto with impunity, for the reason that in them the tuberculous predisposition does not exist. The apparent incongruity between the proof of contagiousness afforded by inoculation in certain of the lower animals, and the uncertain evidence obtained by clinical observation, is to be accounted for by the fact that for the contagion to be effective the predisposition is requisite; and this predisposition does not exist in all persons or at all times in the same person.

The most fruitful source of tuberculous infection is to be found in dried phthisical sputum. Experiments have shown that currents of air do not carry bacteria off from fluids or moist surfaces, but when the substances containing the bacilli are dry, these organisms are readily transported with particles of dust in the atmosphere. Tuberculous infection may come from the lower animals, but probably much less frequently than from the human body.

That it may come from the milk of tuberculous cows is certain. In children especially it is liable to be derived from this source.

[The identity of bovine and human tuberculosis is thoroughly established, and the transmission of tuberculosis through the medium of the alimentary canal is proved by hundreds of laboratory experiments. Interested parties have raised the objection that the portions of beef employed as food, which are chiefly the muscular tissues, are free from bacilli even in animals whose viscera are tuberculous, and that, therefore, if the tuberculous organs are rejected the remainder may be eaten with impunity. This question has been subjected to the test of experiment. The juice of the muscular tissues of tuberculous oxen has been expressed and inoculated in animals, with the result of making them tuberculous.

It has also been argued that tuberculous meat may be rendered innocuous by cooking. That it may be so sterilized is obvious, but practically this is scarcely ever accomplished. All "rare" portions of meat—i. e. all portions in which the albumen is not coagulated—have not been exposed to a temperature high enough to destroy any bacilli that they may contain. These facts demonstrate the importance of systematic inspection of all meat prepared for human consumption, and the absolute rejection of all that is tuberculous.—H.]

Facts show the tuberculous predisposition or diathesis in a certain proportion of cases to be congenital and inherited. Why a peculiarity of constitution rendering a person specially liable at a certain age to this disease should be transmitted from parent to child, cannot be explained, any more than the fact that peculiar traits of physiognomy or of mental character are inherited. The conclusion rests on observation. It is a matter of common remark that the offspring of consumptive parents often become tuberculous. But it is to be borne in mind that owing to the frequency of the disease a tolerably large proportion of phthisical patients must have a consumptive parentage from mere coincidence; and it may be true that, sufficient consideration not having been accorded to this fact, hereditary influence has been overrated. Facts show that the tuberculous predisposition is sometimes inherent in the constitution and inherited. [They also show that the bacillus itself—the seed—may be directly transmitted from parent to child. Landouzy and Martin have inoculated animals with the apparently healthy tissues of the fœtuses of tuberculous mothers, the result being the transmission of tuberculosis.¹

Another method by which the direct transmission of tuberculosis may be demonstrated is by inoculating a pregnant animal with the disease and observing the effect upon the offspring. This experiment has been performed by Galtier,² with the result that three out of a brood of five rabbits exhibited tuberculous lesions at birth.—H.]

The predisposition has relation to age. The disease is most liable to be developed between twenty and thirty. The other decennial periods of life are arranged in the following series, according to the rate of predisposition: thirty and forty, ten and twenty, forty and fifty, fifty and sixty, birth and ten, sixty and seventy, seventy and eighty, eighty and ninety, ninety and a hundred. No age is exempt from a liability to the disease, and it may affect the fœtus *in utero*. Tuberculous cavities are rare in infancy. Dr. Leuf of Brooklyn, N. Y., has communicated to me a case in which cavities existed in a child not quite six months old.

Climate appears to exert an influence either for or against the development of the disease. The prevalence of the disease is less in climates either uni-

¹ Verneuil, *Étude sur la Tuberculose*, vol. i., 1887.

² Vide Arloing, *Leçons sur la Tuberculose*, 1892.

formly warm and dry or uniformly cold and dry than in those which are moist and subject to frequent alternations of cold and warmth. A high altitude seems to afford protection against the disease. Jaccoud states that observations for fifteen consecutive years warrant him in asserting that in Alpine situations elevated 4000 feet tuberculosis is almost unknown; and especially is this true of villages at an elevation of 5500 feet, where, in the language of the country, there are "nine months of winter and three months of cold weather." According to Dr. Hjaltelin, who resides in Iceland, the inhabitants of that country enjoy exemption from phthisis. The disease prevails to a much greater extent in cities than in the country. The researches of Bowditch go to show that in the State of Massachusetts cases occur more frequently in places in which the atmosphere is rendered humid by streams or marshes. Dr. Buchanan's observations show that in England cases are comparatively rare in dry, elevated situations. There is no foundation for the opinion that malaria affords any protection against the disease. Newly-settled places are frequently exempt for some time from its prevalence to much extent; but the explanation of this fact is that the pioneers who compose the early population in these places are persons generally of sturdy, vigorous health, and the habits of life in such a population are protective against this disease. As regards season, the disease is oftener developed during the spring months and the hot months of summer than at other seasons of the year. The disease prevails more among those whose pursuits are sedentary than among those whose occupation involves outdoor life. Want of exercise, defective ventilation, deficiency of light, and the depressing emotions apparently contribute to the production of the tuberculous predisposition.

The infrequency with which the disease is found in the post-mortem examinations of those who have died from intemperance has led to the supposition that the use of alcohol antagonizes the tuberculous predisposition.¹ There is reason to believe that habits of diet unduly restricted as regards variety and quantity, either from choice or necessity, may contribute to the development of the disease.

Pregnancy has been supposed to antagonize the tuberculous predisposition, and marriage has sometimes been advised as a prophylactic and even curative measure. Facts, however, do not afford support to this supposition. In the collection of cases which I have analyzed, 87 were married and under forty years of age. Of these 87 cases, the disease was developed during pregnancy in 10, and in 12 within a few weeks or months after confinement.² The inference is, that pregnancy, either directly or indirectly, has a decided and considerable influence in the etiology of the disease. The researches of Grisolle and Dubreuil show that the development of the disease not infrequently takes place during pregnancy, and when tuberculous patients become pregnant the progress of the disease is hastened rather than retarded.³ Clinical facts are opposed to the notion that the progress of the disease is retarded by lactation.

Certain diseases exert an influence on the one hand to promote, and on the other hand to prevent, the development of tuberculosis. It rarely occurs in persons affected with pulmonary emphysema. Persons affected with cardiac lesions which interfere with hæmatosis rarely become tuberculous. On the other hand, measles and typhoid fever leave the system in a condition favorable for the development of tuberculosis. Are they who suffer in early life from a scrofulous affection of the lymphatic glands of the neck especially

¹ Hérard and Cornil, *op. cit.*

² *Phthisis, in a Series of Clinical Studies*, Philadelphia, 1875.

³ *The Elements of Prognosis in Consumption*, by James Edward Pollock, M. D., London, 1865.

prone to pulmonary tuberculosis in after-life? I have been led to think that this question may be answered in the negative. I have collected a number of cases in which young and middle-aged persons presenting the characteristic cicatrices on the neck were free from tuberculous disease of the lungs; and on the other hand it is rare to find these cicatrices in persons who are affected with pulmonary tuberculosis. Assuming tuberculosis and the scrofulous cachexia to be identical, as has been proved by the presence in both of the bacillus tuberculosis, it would seem that the predisposition is, as it were, exhausted by the affection in the glands of the neck, and that afterward it is not likely to recur. Contrary to what might be expected *a priori*, anæmic persons rarely become tuberculous. The association of anæmia with pulmonary tuberculosis, except as a complication or an effect, is rare. It is rare for phthisis to follow an attack of lobar pneumonitis or acute pleuritis. Statistics show that these affections have not a causative relation to pulmonary phthisis.

Bronchitis, acute or chronic, has no tendency to eventuate in phthisis. This assertion contravenes not only a prevailing popular notion, but a traditional opinion still held by not a few physicians. I make the assertion, however, with the utmost confidence in its correctness, inasmuch as it is based on the study of a large number of cases with reference to the earliest symptoms and signs. Moreover, it accords with the clinical researches of Louis, which, so far as they go, are not less valuable to-day than when they were made, more than half a century ago.

Bronchial hemorrhage (*bronchorrhagia*) was considered by older writers, and recently by Niemeyer, as causative of phthisis. This is an error. Bronchial hemorrhage may occur irrespective of any connection with tuberculous disease, but when a connection exists the latter precedes and is causative of the former.

To the conformation of the thorax was formerly attributed considerable causative agency. This doubtless arose in part from observing that phthisical patients often present contraction of the chest, occurring as an effect of the disease. Persons with great deformity of the chest are not specially liable to phthisis. So also the idea that the exercise of the voice may be a predisposing or exciting cause has become obsolete; and observation shows that if any influence be derived from this source it is conservative rather than causative.

The opinion appears to be entertained by some writers that chronic pharyngitis, which is an exceedingly common affection in this part of the world, has a tendency to eventuate in pulmonary phthisis. This opinion is erroneous. After a large opportunity of observing cases of chronic pharyngitis, I have come to the conclusion that it generally denotes a condition of the system unfavorable to phthisical disease. The sebum-like matter which is liable to accumulate in the glands of the tonsils, and to be ejected by coughing in the form of round hard pellets, is sometimes mistaken for tubercles. These may be distinguished from obsolete tubercles or pulmonary calculi by their being unctuous to the touch and emitting when crushed a fetid odor.

In conclusion, of the agencies concerned in the causation of the tuberculous predisposition, it is difficult to estimate their relative importance. In view of the necessary existence of this predisposition in the development of pulmonary phthisis, this is a diathetic disease; but it is impossible to determine whether the diathesis be always innate, or whether in a certain proportion of cases it is acquired. Do the causes which contribute to the development of the disease produce the diathesis, or do they act as auxiliary causes, the diathesis already existing? Our present knowledge does not enable us to

answer this question. Yet the limited knowledge which we possess is of much value in its practical application to prophylaxis and treatment.

We cannot define anatomically the tuberculous predisposition; in other words, in the present state of our knowledge we are ignorant of the anatomical conditions on which this predisposition depends. We can think of it only as a certain quality of lung-tissue which makes the latter a favorable soil for the multiplication of the tuberculous bacilli. Using the language of metaphor, we may say that the cells are unable to conquer in a struggle for existence with the bacilli. It is probable that those who are naturally resistant to the action of the bacilli may become tuberculous when exposed to the virus in large quantity, as in the case of a wife or a nurse constantly in close proximity to a tuberculous patient.

CHAPTER VII.

PULMONARY PHTHISIS (CONTINUED).

Diagnosis; Prognosis; Treatment.

DIAGNOSIS.—The diagnosis of pulmonary phthisis rests mainly upon an examination of the sputum and upon physical signs. The discovery of tubercle bacilli in the sputum is almost certain evidence of the existence of pulmonary tuberculosis. The possibility of these bacilli being accidentally present in the sputum of persons unaffected by tuberculosis is so slight that it need hardly be considered, and certainly any possible error from this source will be eliminated by examinations of the sputum repeated from time to time. It very rarely happens that bacilli are absent for any considerable length of time from the sputum of phthisical patients. Failure to find the bacilli, however, is less satisfactory as an evidence of the absence of phthisis than is the recognition of the bacilli as an evidence of the existence of phthisis. Nevertheless, when the sputum is repeatedly examined for a long time without the discovery of bacilli, the existence of phthisis is improbable. Cases which are sometimes described as non-bacillary forms of phthisis are generally, in so far as there is no error of observation, cases of some non-tuberculous form of chronic pulmonary disease, particularly chronic bronchitis with bronchiectatic cavities. Bacilli are sometimes very abundant in phthisical sputum; at other times they are few and are discovered only after long search. No definite rules can be laid down as to the relation between the number of bacilli and the rapidity of progress and the extent of the tuberculous disease.

On account of the diagnostic importance of the subject, directions will here be given for staining the tubercle bacilli in the sputum, but it must be mentioned that considerable familiarity with microscopical technique and observation is required for the successful employment of the methods described.

The best method of staining the tubercle bacilli is that devised by Ehrlich. The staining fluid is prepared as follows: Shake thoroughly aniline oil and distilled water in the proportion of about 5 parts of the oil to 100 parts of water. After about ten minutes, filter the mixture through a filter moistened with distilled water. If drops of oil be still present in the filtrate, it is necessary to filter again. To the clear filtrate add enough of a saturated

alcoholic solution of fuchsin or of gentian-violet to produce a dark color, with a slight opalescent scum on the surface. (The alcoholic solution of the staining dye is saturated when after standing a number of days some of the staining substance remains undissolved at the bottom of the bottle. This alcoholic solution can be kept permanently.) The filtered mixture of aniline oil and water may be prepared fresh every time it is used, or a staining fluid of the following composition may be preserved for about two weeks: 100 parts of filtered aniline oil and water, 11 parts of saturated alcoholic solution of fuchsin or of gentian-violet, and 10 parts of absolute alcohol.

In order to prepare the specimen, portions of sputum should not be taken at random, but, if they be present, little whitish or yellowish particles should be selected from the sputum and transferred to a cover-glass, where such a particle is to be spread over one surface of the glass in as thin and as uniform a layer as possible. This is accomplished either by means of a scalpel or needle or by pressing two cover-glasses together and then drawing them apart. The specimen should be allowed to dry thoroughly, and then the cover-glass, with the specimen uppermost, is passed with moderate rapidity three times through the flame of a Bunsen burner or of a spirit-lamp. In this process the specimen should not be burned.

The cover-glass, thus prepared, is now placed, specimen side downward, upon the surface of the staining fluid, where it remains for from twelve to twenty-four hours. The staining process may be hastened, although the results are somewhat less satisfactory, by heating the fluid to beginning ebullition. In this way a specimen may be stained in ten minutes.

The cover-glass, on which the specimen is now deeply stained, is transferred to a mixture of 1 part of pure nitric acid and 3 or 4 parts of water. Here the specimen remains a few seconds, at the most half a minute, after which most of the color is extracted.

From the acid the cover-glass is transferred to alcohol (60-70 per cent.), where most of the remaining color is removed. A few seconds to half a minute in the alcohol suffices. The cover-glass is now removed from the alcohol, and, if necessary, after a second washing in fresh alcohol it is allowed to dry. After it is dry the specimen may be mounted in Canada balsam or it may be examined in xylol, oil of cedar, or, without previous drying, in glycerin, or even in water. After removing the specimen from the alcohol a complementary stain, although it is not necessary, may be obtained by placing the cover-glass for a few seconds in a weak aqueous solution of Bismarck brown (if gentian-violet be employed) or of methylene-blue (if fuchsin be employed).

For recognizing the bacilli it is very desirable to make use of an oil-immersion objective and an Abbe's illuminating apparatus. The tubercle bacilli appear as slender rods about one quarter to one half the diameter of red blood-corpuscles, and frequently curved or slightly bent. They are stained either blue or red according to the staining dye used. The bacilli of leprosy stain by the same procedure as that adopted for tubercle bacilli, but an error from this cause is not likely to occur.

It is particularly important to examine the sputum for bacilli in the early stages of phthisis before the phthisical signs are distinctive. By the discovery of the bacilli in cases of early hæmoptysis great assistance has been rendered in diagnosis.

Elastic fibres are often present in phthisical sputum, even in an early stage of the disease. They afford evidence of destruction of lung-tissue. They may be readily discovered by boiling the sputum for a short time with a solution of caustic potash or of caustic soda (1 to 6), as recommended by Fenwick. The sediment may be collected in a conical glass, and after settling a portion of the sediment may be transferred to a slide by a pipette. The fibres

may be recognized by their glistening appearance and curled shape. Sometimes they preserve their alveolar arrangement.

The physical conditions when the local affection is considerable or when the disease is advanced to the second stage are represented by well-marked physical signs. The diminished volume of lung at the apex causes a depression at the summit of the chest, and, owing to pleuritic adhesions, the expansion at the summit is less than on the opposite side. The scapula on the side most affected is restrained in its movement upward in inspiration, contrasting in this respect with the opposite scapula. These signs, obtained by inspection, are available in a certain proportion of cases. Percussion elicits relative dullness, and sometimes even flatness. Exceptionally, over the solidified portion of lung the resonance is tympanitic. A tympanitic resonance over a circumscribed space and the varieties of this resonance called cracked metal and amphoric denote cavities. The respiratory sound obtained by auscultation is either bronchial or broncho-vesicular or cavernous, and not infrequently these different signs are found in different situations in the same case. The first represents considerable or complete solidification, the second moderate or slight solidification, and the third a cavity or cavities. The cavernous respiration in some cases has an amphoric quality. The correlative vocal signs are usually present—namely, either bronchophony with the loud and whispered voice, or exaggerated vocal resonance, and in rare cases pectoriloquy. More or less of these auscultatory signs are available in the great majority of cases.

It is only in cases in which the local affection is moderate or small, the symptoms being at the same time less marked, that the diagnosis from physical signs is difficult; and the difficulty in such cases is rarely great, provided the physician have a good practical knowledge of physical exploration. Inspection may in these cases furnish the same signs, but less marked than in cases of a considerable local affection. As a rule, slight or moderate but distinct dullness on percussion may be ascertained. The exception to this rule is when more or less of the pulmonary lobules become emphysematous, and then the resonance is altered, although not diminished; it is vesiculo-tympanitic. A comparison of the respiratory murmur on the two sides at the summit will be likely to show abnormal changes—namely, the characters of the broncho-vesicular respiration. So also on a comparison as regards vocal signs, the vocal resonance and the bronchial whisper may be found to be increased. The same is true of vocal fremitus.

In addition to these signs there are several occasionally present which inferentially are evidence of phthisis. These may be distinguished from those already enumerated as the accessory signs of the disease. Fine bubbling or the subcrepitant râles heard within a circumscribed space at the summit of the chest on one side are highly significant of tubercle. They proceed from secondary circumscribed bronchitis. A crepitant râle, in like manner limited to a small space at the summit on one side, has the same significance, being due to secondary circumscribed pneumonitis. Crumpling and crackling sounds are significant, provided they be limited to the summit on one side. A pleural friction sound limited to the summit on one side denotes a secondary circumscribed pleuritis. Other accessory signs are an abnormal transmission of the heart-sounds and an interrupted or jerking respiration. The diagnostic significance of all these signs, it will be observed, depends on their situation at the summit of the chest on one side. Separately, they are not sufficient for the diagnosis, but coexisting with the direct signs—namely, dullness on percussion, broncho-vesicular respiration, exaggerated vocal resonance, and increased bronchial whisper—they serve to confirm these signs and render the diagnostic evidence positive.

The diagnostic points pertaining to symptoms to which attention is to be

directed ~~are~~ as follows: (a) Cough and expectoration, not succeeding an attack of acute bronchitis and not connected with chronic pharyngitis, the cough at first dry, and afterward an expectoration at first small and transparent, and becoming gradually more abundant and opaque. (b) Stitch-pains at the summit, not connected with intercostal neuralgia. (c) Chills not referable to malaria. (d) Hæmoptysis: this is always a symptom of great significance, but the fact is to be borne in mind that it occurs in a certain proportion of cases without being associated with tubercle. (e) Accelerated breathing. (f) Loss of weight. (g) Pallor or anæmia not otherwise explicable. (h) Hoarseness or huskiness of voice proceeding from chronic laryngitis. (i) Chronic peritonitis not traumatic. (j) Suppression of the menses. (k) Buoyancy of mind instead of despondency.

In certain cases the solidification represented by physical signs at the time of an examination of the chest depends to a greater or less extent on an intercurrent, transient, circumscribed pneumonitis. This can only be ascertained by repeated examinations of the chest after certain intervals of time. The solidification, so far as due to superadded simple or ordinary pneumonic inflammation, will be found to disappear, leaving that which is caused exclusively by the phthisical affection. It is important to bear in mind the liability to a temporary increase of solidification of lung in cases of phthisis from an intercurrent pneumonitis which may not reveal itself by any distinctive symptoms.

PROGNOSIS.—The prognosis is extremely unfavorable, in view of the fact that in many if not most parts of the world the mortality from this disease exceeds that from any other, exclusive of fevers and affections which prevail epidemically or endemically. Yet the mortality from the disease has undoubtedly diminished within the past half century. This must be obvious to medical observers whose professional experience extends back for that period. The fact is also shown by the statistics published by the registrar-general of Great Britain and by the mortuary reports of the large cities in this country. The explanation of the fact is to be found in improved views as regards the management of the disease. The diminution which has already taken place in the death-rate from this disease affords ground for the hope that its formidable character may be still further mitigated.

The different modes in which the disease may pursue a favorable course have been already stated. The generations of bacilli may die out or be destroyed, and the tuberculous products may either be absorbed or calcification may occur, forming the so-called obsolete tubercles or calculi; and these may remain quiescent or they may find their way into the bronchial tubes and be expectorated. Cavities may completely cicatrize. In these modes complete recovery may take place. This, of course, is the most satisfactory termination. Next to this is the persistence of cavities without any fresh products, the cavities giving but little inconvenience for an indefinite period, and even through a long life. According to these different modes in which the course of the disease is favorable, cases may be divided into those in which an arrest takes place without recovery and those in which the arrest is followed by recovery. Whether recovery follow or not depends on the extent of the local affection and other circumstances. Not infrequently the disease ceases to progress, with or without recovery, and after the lapse of months or years a recurrence occurs. The latter, then, is not properly a continuance of the disease, but a renewed invasion by bacilli.

The facts relating to the proportion of instances in which the disease ceased to progress, either with or without complete recovery, as developed by the analytical study of the collection of cases recorded by me during a

period of thirty-four years, are as follows: Of 670 cases, the list embracing a few cases of acute tuberculosis and interstitial pneumonia, 44 ended in recovery. In my work on *Phthisis*, published in 1875, the details of the history of each of these cases are given sufficiently to render evident the correctness of the diagnosis and the fact of recovery. In 31 cases the disease was either arrested or ceased to progress, complete recovery from the lesions incident thereto not taking place. Thus, in 75 cases either recovery took place or the disease became non-progressive. The ratio of recoveries (1 to 15) is not fairly shown by these facts, inasmuch as the termination in a considerable number of cases was not ascertained. This statement of course applies equally to the ratio of cases in which the disease is either arrested or its progress ceases without recovery. A fair conclusion is that in not an extremely small proportion of cases complete recovery may be hoped for, and that this conclusion is equally true in respect to the disease becoming non-progressive without complete recovery. A recurrence of the disease after periods varying from one and a half to more than six years was noted in 6 cases. In 5 of these cases the recurrent disease terminated fatally. In the single case in which the recurrent disease did not prove fatal a second recurrence took place more than twenty years ago, the patient now living and being free from any pulmonary affection.

I may claim, in behalf of my clinical studies in relation to phthisis, the establishment of the fact that in a certain proportion of cases this disease is self-limited; in other words, it ends in recovery from an intrinsic tendency thereto. Of the 44 cases ending in recovery, in 23 there was no medicinal treatment to which an arrest of the disease could be attributed. In several there was no medicinal treatment whatever, and in the remainder the treatment consisted of simple tonics, cough palliatives, or remedies to meet other symptomatic indications. In none could the treatment be considered as curative. Of the 31 cases in which the disease became non-progressive without complete recovery, in 15 there was no medication by which, as might be supposed, the disease was controlled, and in several none whatever. In respect to hygienic treatment, in some cases of both groups there was no change whatever in the habits of life; in other cases there were changes involving more favorable circumstances pertaining to hygiene; but in a considerable number those changes were not of such a character that a potential influence could be attributed thereto. It is probably correct to say that the changes may have favored recovery or non-progression, but were inadequate to cause an arrest of the disease. The histories in these ten groups substantiate self-limitation in cases of phthisis. The disease may cease to progress and end in recovery because it is self-limited.

Assuming that phthisis in a certain proportion of cases is a self-limited disease, the practical bearing on the conclusions to be drawn from medicinal and hygienic treatment is important. If the disease may end in recovery exclusively from self-limitation, this must be more or less operative in the cases which recover under different measures of treatment. Self-limitation is a factor co-operative in certain cases with curative measures, and, it may perhaps be added, sometimes effective in spite of measures which tend to obstruct its operation. On the other hand, when this factor is feeble or wanting curative treatment is not likely to prove of much avail. Evidently, in drawing conclusions respecting the curative effect of remedies allowance is to be made for this factor. The extent of its co-operation doubtless differs much in different cases, in some being sufficient in itself, and in others either considerable, moderate, or slight. Considering that its agency has not been hitherto recognized, it is easy to explain the well-known fact that from time to time various methods of treating phthisis apparently successful in some

striking instances have failed speedily to meet the expectations excited by their apparent success. Whatever was really due more or less to self-limitation was attributed solely to the methods of treatment, and when the former was feeble or wanting the latter gave little or no evidence of curative power. This is the rationale of the "*post hoc, propter hoc*" fallacy which has always had much to do with false deductions from therapeutical experience.¹

The most rational explanation of the manner in which this disease ends by self-limitation is to suppose that the conditions which are essential for the multiplication of the bacilli, and which constitute the tuberculous predisposition or diathesis, after a time cease to exist. The vegetable parasite is destroyed because the soil becomes incapable of maintaining longer its existence. These conditions, it may be supposed, are greater and more enduring in some persons than in others, and the variation in this respect explains the differences in different cases of phthisis as regards the period in the progress of the disease when the ending by self-limitation takes place. In our present ignorance of the nature of the conditions on which depend the life of a parasite, our information in respect to the foregoing question must be derived from clinical observation.

The symptoms which warrant hope, and sometimes an expectation of a favorable course and termination, relate especially to the circulation, the body-heat, alimentation, and nutrition. Persistent frequency of the pulse, fever, anorexia, and progressive emaciation oppose reliance on self-limitation. *Per contra*, encouragement on this score is warrantable when the pulse is but little if at all more frequent than in health, the temperature of the body not much if any raised, the appetite in a great measure retained, and loss of weight inconsiderable. These and other symptomatic conditions which render it possible if not probable that the disease tends intrinsically to recovery may be summed up in one word—tolerance. In proportion as phthisis is well tolerated there is room for hoping that it will prove self-limited. If the tolerance be deficient, self-limitation is proportionably weak or wanting. Other things being equal, the chances of recovery by self-limitation are greater the smaller the amount of phthisical lesions and the space in which they are localized. I have been led to believe that phthisis not infrequently ends by self-limitation before it has made sufficient progress to develop well-marked physical signs. In other words, there are abortive cases of this as of other diseases. How often are the traces of an old, small phthisical affection found in bodies dead with various diseases. [Many years ago, Prof. Hughes Bennett of Edinburgh made a series of observations with reference to this point, and found signs of arrested tubercle in the lungs of from one-third to one-half of all individuals dying over the age of forty. Similar observations in the Paris hospitals (Salpêtrière and Bicêtre) resulted in the discovery of healed tuberculosis in the lungs of more than one-half the patients dying over seventy years of age.—H.] I have met with not a few instances of, as I supposed, abortive phthisis. These cases are likely to be misapprehended, the more so because the general belief is that exceptions to the rule of progress are extremely rare.

I have learned, however, from histories which I have recorded and reported, that self-limitation may be exemplified notwithstanding a large area of solidification followed by cavities of considerable size. The most reliable of the points on which a hopeful prognosis is to be predicated in these cases is the confinement of the affection within circumscribed limits; that is, absence of signs denoting progressive extension or general diffusion. The extent and degree of lesions, if circumscribed, do not prevent the disease from being

¹ Vide paper entitled "Self-limitation in Cases of Phthisis," by the author, in the *Archives of Medicine*, New York, June, 1879.

self-limited, but they stand in the way of complete recovery. In most of the cases of non-progressive phthisis without recovery the lesions do not admit of restoration, although the phthisical disease may be said to have ceased; the lesions in these cases remain as sequels, like, for example, the intestinal ulcerations resulting in tropical climates from acute dysentery.

It is doubtful if any definite conclusion can be drawn from the number of bacilli in the sputa as regards the tendency to self-limitation. The complete disappearance of bacilli, however, in a series of specimens is proof that the tuberculous disease is arrested.

Aside from the symptoms and signs to be taken into account in forming a judgment respecting self-limitation, my clinical studies have shown that age and sex have no special significance. They show, what could not have been anticipated, that heredity is not incompatible with an intrinsic tendency to recovery. I will add that my histories afford evidence that profuse and repeatedly occurring hæmoptysis, chronic laryngitis, pleurisy with effusion, and perineal fistula are by no means in all cases unfavorable as regards prognosis based on self-limitation.

The disease proves fatal generally by asthenia. It is rare for the destruction of lung to be so great as to destroy life by apnœa. The patient is gradually worn out by the protracted disturbance occasioned by the disease, conjoined with progressive emaciation and exhaustion. The development of pneumo-hydrothorax from perforation may prove fatal in a short time, and then sometimes by apnœa. Acute peritonitis from perforation has been known to occur, and this affection is likely to prove rapidly fatal. Meningitis is another complication which hastens the fatal termination.

Hæmoptysis is very rarely an immediate cause of death. A few such instances, however, have fallen under my observation. A profuse and rapid flow of blood may occasion death by suffocation, the blood filling the bronchial tubes. A case of this kind has fallen under my observation. In two cases among those which I have analyzed death was attributable to profuse hemorrhage from a phthisical cavity. The analytical studies of Ware and Walshe proved that, as a rule, hæmoptysis is a favorable event as regards prognosis. My own clinical studies led to the conclusion "that cases in which hæmoptysis occurs show a larger number of recoveries, and a notably greater proportion of instances of arrest and of tolerance, than cases in which hæmoptysis does not occur."

Dunin has reported the sudden death of a patient affected with phthisis, in which air was found in the blood-vessels, the source of the air not being discoverable and no other cause of death being apparent.

Vogel has reported a case in which a cheesy affection of a bronchial gland led to a communication between a bronchial tube and the right subclavian vein, causing sudden death.

Duguet has reported a case in which a thrombus from the crural vein gave rise to embolism of the pulmonary artery and sudden death, the symptoms of phlegmasia dolens not having been present.¹

TREATMENT.—Regarded from a rational standpoint in the light of the parasitic doctrine, the treatment of phthisis has reference to two objects. The first object is the destruction of the parasite by the direct agency of some substance which is either inhaled or introduced into the blood. Various agents destructive out of the body to bacteria have already been employed by inhalation, but thus far without encouraging results. The great obstacle in the way of thus directly destroying the parasite is the diffi-

¹ *Virchow u. Hirsch's Jahresbericht*, 1882.

culty of the conveyance of the parasiticide in the form of either an injectable powder or in vapor to the colonies of the parasite, without the employment of this agent in a quantity sufficient to prove a source of danger. It remains for further experimental observations to furnish data for determining whether the progress of this disease can be arrested by disinfecting agents brought into contact with the parasite by means of the circulation. It is possible that some of the remedies which experience has shown to be useful may act as parasiticides. The second rational object of treatment is the removal of the tuberculous predisposition or diathesis. In the present state of our knowledge the prospect of success in arresting the disease or retarding its progress depends on the successful employment of measures for this object. In our ignorance of the nature of the conditions expressed by the terms tuberculous predisposition and diathesis our present knowledge of these measures must be derived wholly from clinical experience.

It is of course immensely desirable for the arrest to take place as quickly as possible while the local affection is limited and the pulmonary danger proportionably small; and with a view to a speedy arrest the importance of an early diagnosis can hardly be overrated.

Is the tuberculous predisposition or diathesis removable by any known special remedy or remedies? This question is to be answered in the negative. Various remedies have been supposed to exert a specific curative influence. Thus within the last half century wood-naphtha, cod-liver oil, phosphate of lime, the hypophosphites, the chlorate of potassa, and the benzoate of soda have successively been advocated as effecting a cure in cases of pulmonary tuberculosis. Few if any at the present moment consider these or any other remedies as specifically curative. This, however, is by no means saying that remedies are not useful in cases of pulmonary phthisis. Important indications are to be fulfilled by remedies, but in the present state of our knowledge more reliance is to be placed on hygienic than on medicinal measures of treatment.

Certain therapeutic measures heretofore employed, to a greater or less extent, under the guidance of false pathological views, do harm rather than good. In this category belong bloodletting, either general or local, blisters and other severe modes of counter-irritation, mercurialization, antimonial and other nauseating preparations, emetics, and cathartics. These are contra-indicated. In general terms, everything is to be avoided which tends to impair the appetite, disorder digestion, and lower the vital powers.

The measures which clinical experience has shown to be useful, and sometimes effective, in either arresting or retarding the progress of the disease, are those which strengthen and invigorate. These terms, although lacking scientific precision, have a practical significance sufficiently intelligible. Directing attention to the measures which fall under the head of hygiene, these relate to diet, exercise in the open air, clothing, mental encouragement, and change of climate.

The diet should be generous as regards quantity, quality, and variety. The articles should be highly nutritious and adapted to the digestive powers. All the varieties of wholesome food which the patient is able to take with relish should be allowed, and the appetite should be encouraged as much as possible. With respect to the kinds of food to be particularly recommended, there are no general rules applicable to all patients. Meats, milk, farinaceous articles, and the different vegetables are to be combined in relative proportions according to the choice, habits, and experience in individual cases. It is desirable that cream, butter, and other fatty articles should enter into the diet as largely as possible without inducing disgust and disorder of digestion.

The same remark applies to sugar. The intervals between taking food should be such as will secure the largest amount of nutriment which can be taken and digested during the twenty-four hours. In short, it is far from desirable to arrange any fixed system embracing details of dietetics to which all patients are expected to conform. The object is to nourish the body to the fullest possible extent, and this requires in every case the co-operation of the physician and patient. Deficiency of appetite, especially for nutritious articles of diet, and weak or disordered digestion, are serious difficulties in the way of successful management. Much may be done by persevering efforts on the part of the patient, and he should therefore be made to understand the object which it is desired to attain.

A diet consisting largely, or even chiefly, of fresh milk has undoubtedly proved sometimes successful, and a trial of it may be advised when the appetite is deficient or when other articles of food occasion dyspeptic disorders. Goat's milk, mare's and ass's milk, are rarely used in this country. They have heretofore been, and are still to some extent, in European countries considered as preferable to the milk of the cow. In order to carry out effectually the "milk cure," as it is sometimes called, milk should not only constitute the chief article of diet, but it should be taken largely.

Exercise in the open air—or, as I should prefer to say, out-of-door life—is, of all measures, the most important. In 1863,¹ I analyzed the recorded histories of 62 cases in which an arrest took place, with a view to the points in the treatment which were common to all or a greater or less number. In 20 of these cases the arrest took place under hygienic measures without medicinal treatment. In these cases the most important point of agreement related to change of habits as regards exercise and out-of-door life. In respect to this point there was also an agreement in the cases in which medicinal measures were employed. The following extract from the paper contains a summary of the facts, with the general conclusions: "The most striking and valuable of the results of the analytical study of these cases is their almost uniform agreement as regards change of habits with respect to exercise and out-of-door life at the time of the arrest. Excluding 7 cases in which the arrest was attributable solely to self-limitation, and 2 cases in which the facts with respect to this point were not noted, of the remaining 53 cases, in all save 3 the histories show a greater or less change of habits to have been made; and in many cases the change consisted in relinquishing sedentary callings for other pursuits in order to carry out more effectually the desired reformation. There are grounds for believing that the advantage of a change of climate mainly consists in its being subsidiary to a change of habits as regards exercise and out-of-door life."

Phthisical patients should sleep in well-ventilated rooms. In conformity with popular notions they frequently fear the cool or cold air of night. A fire may be kept in sleeping-rooms in the winter season, but the windows should be kept open. Dr. James Blake of San Francisco, California, has reported several cases in which most favorable results followed living in the open air during the summer months, at an elevation of from 3000 to 5000 feet above the sea, in the Coast Range of the mountains of California, where the temperature is very equable and no rain falls for five or six months. The patients did not even sleep in tents, but were in the open air during night and day.

Exercise in the open air should be accompanied by either mental recreation or occupations which interest the mind. It should, as far as possible, be incidental to pursuits which engage the attention. Adopted simply as a hygienic measure, it will rarely be persisted in. It is often essential, there-

¹ *Trans. N. Y. Acad. of Med.*, 1863.

fore, for patients to make a radical change in business, or, if they be able to devote their time to the restoration of health, hunting, sporting, travelling, etc. are to be resorted to as means of securing the union of out-of-door life with an agreeable exercise of the mental faculties. Over-exercise of the muscles is to be avoided. Patients sometimes, supposing that the benefit from muscular exercise is proportionate to its amount, carry it to the extent of producing a degree of fatigue and exhaustion which is injurious. It is not from the amount of physical exertion, but of out-of-door life with such exercise as is well borne, that benefit is to be expected.

The body should be protected against atmospherical changes, the temperature and functions of the skin being maintained by warm clothing. The garments worn next the surface should be made of a material which is a non-conductor of heat—namely, either wool or silk; but a superfluity of clothing is to be avoided. The object is to provide adequate protection without an undue accumulation of heat and perspiration. In a cold or temperate latitude during the winter season a waistcoat of buckskin or chamois leather, worn during the daytime over a light woollen or silk shirt, is to be recommended to patients of either sex as securing proper protection without the inconvenience of being bundled with an overplus of garments. The feet should be well guarded against cold and wet. Properly clothed, the patient, if he be strong enough to go out of doors, should rarely be kept within doors by the state of the weather, but should resolutely keep up habits of out-of-door life despite the ordinary changes of temperature and winds, remaining in the house only on inclement days.

I have frequently known the sponge-bath to be taken daily by tuberculous patients with apparent benefit. It may be safely tried and continued, provided it be followed by an agreeable glow. The temperature of the water used should be from 64° to 68° F. It is to be borne in mind, with reference to this measure as well as exercise in the open air, that the susceptibility to attacks of bronchitis is less the more the exposure, and also that an attack of bronchitis does not usually exert any unfavorable influence on the tuberculous disease. Many patients are deterred from going out of doors when the weather seems unfavorable, by needless apprehension of taking cold.

The proportion of cases in which an arrest of the disease is apparently either effected or promoted thereby is sufficient to authorize the physician to encourage patients strongly to employ the hygienic measures which have been briefly considered. The influence of the disease on the mind is to induce either an expectation of recovery without effort or resignation to death. It is important to make patients understand that very much depends on their own exertions. One of the difficulties in the way of successful management is a passive, patient, tranquil frame of mind which cannot be aroused to vigorous efforts. Persons endowed with resolution, energy, and perseverance, other things being equal, are more likely to struggle successfully with the disease than they who are deficient in these mental qualities. The measures which have been considered, if not successful in effecting an arrest of the disease, tend to retard its progress and render the condition of patients most comfortable while life lasts.

Change of climate, as a means of effecting a cure of pulmonary tuberculosis, has been a fruitful topic of discussion. It does not fall within the scope of this work to enter into a full discussion of this question. I shall present briefly certain considerations in connection with the question in individual cases, "Shall I try change of climate? and if so where shall I go?"

It may be assumed that a change of climate is frequently useful, and it appears sometimes to effect an arrest of the disease. The judgment of patients or their friends in the matter is not of much value, because it is usually based

on the knowledge of a few cases, or perhaps of a single case, in which benefit may or may not have been apparently obtained.

It may be taken for granted that there is no specific influence in any climate. It would be therefore needless to inquire if there be one particular place on the globe to be preferred above all others. Observation shows that different climates are suited to different cases. In general, the advantages which belong to climate pertain to altitude, uniformity, and dryness. As regards the latter, while a dry climate is generally preferable, some patients appear to do best in situations in which the atmosphere is warm and humid. With respect to temperature, a uniform, cold climate is best for some cases, and a uniform, warm climate, for other cases. Of late years the custom has been gaining ground of sending patients to a cold latitude, and I have known of a number of instances in which the climates of Minnesota and Colorado have proved highly serviceable. Altitude is a marked element in these climates, as in St. Moritz and Davos in Switzerland. On the other hand, I have known of many instances in which a change to a warm climate has appeared to accomplish all that could be desired. What circumstances are to guide in deciding whether a cold or a warm climate will be likely to prove more advantageous? The feelings and choice of the patient are to have considerable weight. If when in health more vigor and enjoyment are experienced in summer than in winter, a warm climate will probably be better, and if the reverse be true a cold climate is to be preferred. The condition of the patient as regards feebleness is an essential point. If so feeble as not to be able to live out of doors in cold weather, or if the reaction from the impression of cold be slow and imperfect, a warm climate is more suitable. It is rarely proper to send patients to a cold climate if the disease be considerably advanced, and, as a rule, a cold climate is better suited to men than to women. These remarks with respect to temperature will necessarily apply to climates of which a high altitude is a prominent feature.

With reference to the particular place to be selected, it should contain resources for occupation and mental interest. There must be inducements for out-of-door life. I have known patients accustomed to active habits to suffer intolerably from ennui in going to places where the supposed excellence of climate was the only inducement. It is often better to move from one place to another than to remain stationary; as soon as a place becomes tiresome it is best to leave it. Travelling in foreign countries without any special regard for climate is often the best plan, the advantage consisting in the interest and inducements to out-of-door exercise derived from a succession of new scenes. A sea-voyage in warm latitudes is generally useful, and if patients be fond of the sea a long voyage, if practicable, may be advised. Many patients under my observation have resorted to sea-voyages; and I can affirm that while in not a few instances the benefit has been marked, I have never known any harm to ensue. I have known several instances in which patients in an advanced stage of the disease, the strength being much reduced, have taken long voyages with notable improvement. A change is often useful when there is no superiority on the score of climate, because it is in this way only, in certain cases, that relief from the cares and anxieties of business can be secured. As a rule, it is desirable to avoid places which are specially resorted to by phthisical patients, for the reason that seeing constantly examples of the different phases of the disease is likely to have an unfavorable moral effect. On this score sanatoria for phthisical patients are open to objection. Well-managed sanatoria, however, may have advantages relating to the systematic employment of regiminal measures, to diet, etc.

The habits and tastes of the patients are to be considered. Persons who are dependent on the associations and comforts of home and friends for their hap-

piness will not be likely to be benefited by being sent away, especially if alone and among strangers. The stage of the disease and the rapidity of its progress are points of great importance. It is cruelty to send to a distance patients who are in a condition admitting of but little prospect of improvement, and who will probably not live to return. The symptoms and the amount of damage which the lungs have sustained, as determined by physical signs, are to be taken into account before deciding with regard to change of climate; and if a change be made and prove effectual, it becomes an important question whether, if practicable, the change shall not be permanent. The safest course, undoubtedly, is to take up a residence in a climate in which the disease is less liable to be reproduced than in the climate in which it has been already developed. Finally, in forming an opinion of the importance of change of climate it is to be considered that the progress of the disease will be unfavorable in a large proportion of cases, whatever may be the change or changes made. An arrest of the disease is not to be expected, save in a minority of cases. The fact that of the persons who make trial of change of climate the number who are not apparently benefited greatly exceeds the number who find this measure either successful or beneficial should not discourage resorting to the measure so long as in a small proportion of cases it proves effective. Another consideration is to be added—namely, a change of climate not infrequently appears to retard the progress of the disease, rendering the patient more comfortable and prolonging life, although an arrest of the disease be not effected.

In my series of clinical studies relating to phthisis¹ I endeavored to deduce some conclusions from the cases in which change of climate entered into the histories. In 74 cases this was an important, and in some instances the chief, measure of treatment. Of these 74 cases, in 9 the disease ended in recovery, and in 13 it became non-progressive. The proportion of 22 out of 74 cases is large enough to warrant the conclusion that a salutary influence was due to climate. Moreover, studying the histories closely, it appeared that in 34 additional cases there was evidence of improvement, leaving only 11 cases in which no benefit followed the change of climate. While self-limitation doubtless played an important part, it cannot account for these results to the exclusion of climatic influence.

The results relate to different climates collectively. A great number of places were resorted to by different patients—Minnesota, Colorado, California, New Mexico, the Southern States of the Union, Nice, Mentone, Egypt, South America, etc. My cases were insufficient to determine the comparative value of different climates. In undertaking to do this we have to deal with a complex problem. A fair comparison would require the histories of a considerable number of patients in each one of the various resorts embraced within the range of inquiry. There must at least be an approach to uniformity in all the cases as regards the stage of the disease, the extent of the local affection, and other circumstances. No single observer can accumulate data sufficient for such an undertaking. It would, however, be fair to take the results of all climates as a standard for reference, and bring into comparison the results of the analytical study of a considerable number of cases observed at any one or a greater or less number of the different places of resort. This might be done by observers residing in these different places. In this way very valuable data could be obtained for judging of the comparative advantages of different climates. The value of such data would be incomparably greater than any theoretical opinions in regard to altitude, dryness of the atmosphere, temperature, the presence of ozone, pine-woods' exhalations, etc. If, in addition to comparing results in particular places with those of different climates collect-

¹ *Op. cit.*

ively, a comparison were to be made with the proportion of cases in which there is either recovery or cessation of progress without change of climate, it would be practicable to estimate, with some approximation to accuracy, climatic influences disconnected from the accessory circumstances, prominent among which is self-limitation. Single examples of recovery, however remarkable, are entitled to little weight as evidence of the curative effect either of climate or of any particular measure of treatment. In some of the most striking of the instances which have fallen under my observation the recovery took place without change of climate and without any important medication.

In conclusion, while it must be a great relief to physicians to have formed convictions which prompt a ready and positive answer to the question so often asked, "What part of the world is best suited for phthysical cases?" it will be long before such convictions can have as a basis adequate numerical facts. Meanwhile, they whose minds are not committed to a belief in the superiority of a particular climate over all other climates must exercise judgment according to circumstances in individual cases as regards, first, the propriety of a change; second, the climate to be selected; and third, whether or not a change should be permanent.

As coming within the scope of hygienic management, marriage may be referred to. Physicians are sometimes consulted respecting the propriety of fulfilling a marriage engagement when one of the parties is affected with phthisis. My clinical studies (*op. cit.*) go to show that the effect of marriage on a phthysical patient, irrespective of pregnancy, is not unfavorable—a conclusion perhaps at variance with the opinion generally held. Regarded from a purely medical standpoint, the objections relate to the unfavorable influence of pregnancy if the wife be affected, the risk of phthysical offspring, and the possible communication of the disease from the husband to the wife and *vice versa*. The physician should state these objections. Whether, regarded from other points of view, they should prevent marriage in particular cases is not a question for him to decide. My experience is that, whatever advice be given, the sentiments determine the action in these cases.

Passing to consider remedies which enter into the management, I place under this head alcohol, without discussing the question whether it be properly so regarded, or whether, as was claimed by Todd, it be alimentary rather than medicinal. Clinical experience shows that in a certain proportion of cases alcohol has a salutary effect. In some cases this effect is marked; in other cases alcoholics in any form are not well tolerated, and if their use be persisted in they may prove hurtful. If the immediate effect be that of a cordial—that is, if they produce a sense of comfort; if they be followed by a feeling of increased strength and a greater disposition to exercise; and if they do not excite the circulation or nervous system,—benefit may be expected from their use. *Per contra*, if their immediate effect be discomfort; if they be followed by a feeling of increased weakness and less disposition to exercise; and if they excite the circulation or nervous system,—they will not do good, and they may do harm.

As regards quantity, they may be given as freely as they can be taken without discomfort, without a sense of weakness or indisposition to exertion, and without excitation of the circulation or nervous system. The limitation in quantity is to be determined by the same circumstances which indicate their use, or, in other words, by their immediate effect. And, guided by these circumstances, it will be found that some patients will tolerate a large, some a moderate, and some only a small quantity. Phthisis is one of the diseases which in certain cases induce a remarkable tolerance of alcohol. Some patients who cannot take, without excitation, alcohol in any form in consid-

erable doses, are able to take it without this effect, and with benefit, in a very small quantity repeated after short intervals.

The form to be used is another practical point of inquiry. Whatever be the form used, I believe the remedial principle to be alcohol. But no one form is equally applicable to all cases. Some patients are benefited especially by spirits, some by wine, and some by malt liquors. The selection of the form to be used in individual cases must be decided by the preference of the patient and experimental trials. As a rule, food should be taken with alcoholics.

The extracts of malt now in vogue cannot be regarded as substitutes for alcoholics, and it seems absurd to attribute to them anything beyond a certain amount of alimentary value.

With regard to cod-liver oil, without discussing the propriety of classing it among remedies, I proceed to state the practical points connected with its employment in cases of phthisis. All clinical observers unite in according to it more or less value. Its usefulness in a certain proportion of cases can hardly be doubted. Of the cases of arrested or non-progressive phthisis which I have analyzed, in several the treatment consisted exclusively in the use of cod-liver oil and hygienic measures. How much importance is to be attached to an intrinsic tendency to recovery and how much to hygiene in these cases cannot be determined, but an examination of the circumstances belonging to the individual histories goes to show that a certain amount of salutary influence belongs to the oil. Practically, the question of the use or non-use of the oil relates to individual cases. Clinical observation shows that it is not useful in all cases. I shall give, briefly, the rules which my own experience has led me to adopt respecting its use and non-use.

If it be taken without great repugnance, if it do not impair the appetite or digestion, or occasion derangement of the bowels, it may be expected to do good. If it produce any of the effects just named, its propriety is questionable. It is best to begin with a small quantity and increase to the maximum quantity, which is from half an ounce to an ounce three times daily, taken near the time of meals, either before or after, as choice or experience may dictate. It is generally best tolerated after meals. Of the different oils, some patients tolerate best the pale and others the brown variety. I have repeatedly known patients to take by preference the crude oil obtained at fish-markets. If the pure oil be not well tolerated, some one of the preparations containing lime or other ingredients to divest it of its repulsiveness may be substituted. Of course, in a given volume of the latter patients get a quantity of oil diminished by the bulk of the added material. Observations made by Dr. A. H. Smith and other members of a committee of the New York Therapeutical Society show that the addition of fifteen minims of ether to each half ounce of oil enables patients to take this remedy when, without the addition of the ether, it disagrees. The ether may sometimes be given with advantage half an hour after the oil has been taken.¹ Caoutchouc dissolved in the spirits of turpentine and prepared as a confection, has been largely used by Dr. T. R. Varick, instead of the cod-liver oil, with apparent benefit.² Glycerin has been thought to be useful as a carbonaceous medical food.

Arsenic is supposed by some to exert a certain influence on phthisis. The testimony based on clinical experience by different observers is discrepant. It is a fair conclusion from this fact that the remedy is sometimes useful and sometimes without any appreciable utility. My own experience leads to this conclusion. In a certain proportion of cases it appears to be useful. In order to secure benefit from it the remedy should be given in small doses—one or

¹ Vide *N. Y. Med. Journ.*, March, 1879.

² Vide *N. Y. Med. Record*, Nov. 1, 1873.

two minims of Fowler's solution—repeated three or four times daily. The doses should not be increased. The remedy in small doses may be continued for a long period, but if the dose be increased its toxical effects are liable to occur and its discontinuance becomes necessary. This is an essential point in the use of this remedy in cases of phthisis.

The hypophosphites have been much used in the treatment of phthisis within the last ten years, and as regards their utility there is the same discrepancy of testimony as with respect to arsenic. The same conclusion may be drawn from this fact as in the instance of arsenic. They are useful in a certain proportion of cases. Arsenic and the hypophosphites may be given in combination.

The bichloride of mercury is another remedy which, like the two foregoing remedies, is considered by some observers to have a curative influence. It is possible that whatever efficacy pertains to arsenic, phosphorus, and mercury is due to a direct effect upon the parasite; that is, they act as parasitocides. This remark will perhaps also apply to alcohol. It is, however, a more probable supposition that these remedies modify favorably, in some manner, the conditions on which depends the existence of the parasite. Arsenic is not destructive to the bacillus tuberculosis out of the body.¹

[It is impossible to enumerate the remedies that have been prescribed, and with apparent benefit, in the treatment of pulmonary phthisis. At present the one which is most widely employed and inspires the greatest confidence is undoubtedly creosote. Favorable results from the continued use of this drug are published in all quarters of the globe. Its effects are manifested in the course of from one to two weeks by diminished cough and expectoration, increased strength and weight, improved appetite, and cessation or diminution of night-sweats. Bouchard in a recent communication² states that he has frequently observed patients to increase in weight to the extent of from thirty to forty pounds after being placed upon the use of creosote, and that 55 per cent. of his cases have derived benefit from the drug. Without entering into further details, it must suffice here to state that there is a general consensus of opinion in favor of the employment of creosote in the treatment of pulmonary phthisis. The drug has been administered in every conceivable way—by the mouth, by hypodermic injection, by rectal injection, by inunction, by inhalation, and finally, mingled with olive oil, it has been injected directly into the trachea and bronchi. Enormous doses have been given by the mouth, but it is doubtful whether these "creosotic orgies," as they are styled by Daremberg, are justifiable. Sommerbrodt, whose experience with creosote extends over many years, obtains the best results with moderate doses. It is doubtful whether it is ever necessary to exceed 15 or 20 drops *pro die*, although it may be given in much larger amounts, provided a toleration for the drug be gradually established. Thus, for example, Edwin E. Graham of Philadelphia has administered as much as 72 drops thrice daily. A good vehicle for the drug is milk, but it may be prescribed in pill, capsule, or alcoholic solution. The following are well-known formulæ, the dose mentioned being the minimum:

R. Creosot.,	℥ xl;
Tinct. gentian.,	ʒiiss;
Spirit. rect.,	ʒiiss;
Vin Tokay,	ad ʒvj.—M.

S. One teaspoonful in a glass of water three times a day.

¹ Vide *Verhandlungen des Vereins für innere Medicin zu Berlin*, 1884.

² Vide Daremberg, *Traitement de la Phthisie Pulmonaire*, 1892.

R. Creosot.,	℥ xxx ;
Tinct. aromat.,	ʒj ;
Æther acet.,	ʒj ;
Syr. simp.,	ʒiiss ;
Aq. destillat.,	q. s. ad ʒvi.—M.

S. One teaspoonful in half a glass of water three times a day.

R. Creosot.,	ʒss ;
Tinct. gentian.,	ʒj.—M.

S. 3 to 30 drops three times a day.

If used hypodermically, a drachm to a drachm and a half of a 10 per cent. solution of creosote in the oil of sweet almonds may be employed. For inhalation the following formula is recommended:

R. Creosot.,	gtt. x ;
Spirit. chloroformi,	gtt. x ;
Alcohol.,	gtt. xx.—M.

Guaiacol, which is the chief therapeutic ingredient of creosote, has been largely employed of late instead of the latter. It may be given by the mouth, in pill, or subcutaneously, dissolved in olive oil. The dose is practically identical with that of creosote, in which it sometimes exists to the amount of 90 per cent.

Walzer of Aix-la-Chapelle has recently treated a number of cases with benzoyl-guaiacol, which is a crystalline combination of benzoic acid and guaiacol. It is insoluble in water and other ordinary vehicles, but, being free from unpleasant taste, may be given with powdered sugar to which has been added a little oil of peppermint. In the stomach and small intestine it splits up into guaiacol and benzoic acid. Walzer reports improvement in a number of cases treated with this drug, and it may be resorted to with a certain degree of confidence when creosote and guaiacol are not well borne.—H.]

All remedies which improve appetite, digestion, assimilation, and nutrition are in a greater or less degree useful. Hence quinia, salicin, strychnia or nux vomica, the bitter tinctures or infusions, and the mineral acids meet indications in cases of this disease. The chalybeate tonics are not without utility. That they favor the occurrence of hæmoptysis is an opinion not well grounded, and had they this effect it might be evidence for rather than against their utility.

Certain pulmonary symptoms claim attention. Expectorant remedies, as a rule, are not called for. They diminish appetite, occasion nausea, and disturb digestion. But remedies to allay superfluous cough—that is, cough not required for expectoration—are useful. For this end the succedanea of opium—namely, hyoscyamus, conium, belladonna, hashish, chlorodyne, and hydrocyanic acid—may be prescribed, but if these prove inefficient, opium in some form is required. The paregoric elixir will often suffice. Patients should be instructed not to yield to the disposition to cough, but to resist it whenever it is not effective. The habit of coughing unnecessarily is, in a great measure, under voluntary control. Soothing inhalations are sometimes useful in allaying the irritation which excites cough. The vapor of water or spray impregnated with conium or opium may be inhaled. I have known the vapor of chloric ether to be highly useful as a palliative. All irritating inhalations are hurtful. The oxalate of cerium, in doses of from 5 to 10 gra.

three times daily, has been employed with much success as a cough-palliative. Its effect upon the stomach is that of a tonic.¹

With reference to the injection of tuberculous cavities with a solution of the nitrate of silver or other medicated liquids through the larynx and trachea, it is sufficient to say that, aside from the difficulty of the operation and the impossibility of limiting the application of the injected liquid to cavities, a palliative effect is all that can be expected from this measure were it never so successfully executed. This statement applies to the injection of cavities after making an opening into them through the chest-wall. Prof. Pepper has reported 12 cases in which two hundred and ten injections into cavities were made, the objects being disinfection of the cavities and the promotion of cicatrization. In no instance was harm done, and the apparent results in several instances were beneficial.¹

Certain complications furnish indications for treatment. Attacks of dry, circumscribed pleurisy call for mild revulsive and soothing applications, such as sinapisms, liniments, or the belladonna plaster. Local bleeding by leeches or cups is never required. The pain incidental to these attacks generally passes off in a few days at farthest. The treatment of coexisting laryngitis will be considered in Chapter XII. Diarrhœa dependent on tuberculous enteritis is to be kept in check by astringents and opiates, the latter being used with as much reserve as is consistent with the object to be attained. Chronic peritonitis claims only palliative measures.

In the progress of the disease symptoms other than those relating to the chest require palliative measures. The night-perspirations are frequently a source of great discomfort. The mineral acids, especially the dilute sulphuric acid and gallic or tannic acid, frequently afford relief. The external application of an astringent, such as alum dissolved in spirit, is sometimes effective. Belladonna or atropia is an effective remedy. [Still more certain in their effect are picrotoxin and agaricin. The former may be given in pill in doses of from $\frac{1}{60}$ to $\frac{1}{30}$ of a grain at bed-time, and if this does not suffice, the pill may be repeated once or twice during the twenty-four hours. Agaricin is equally effective in doses of $\frac{1}{6}$ of a grain thrice daily. Camphoric acid is also a valuable remedy for the suppression of night-sweating, and may be given in doses of from 15 to 30 grains in aqueous or alcoholic solution.—H.] Dyspnœa may be mitigated by ethereal preparations.

Paroxysms or exacerbations of fever are sometimes, in a measure, controlled by full doses of quinia. If the temperature be high this remedy is indicated as an antipyretic. If quinia be not well tolerated or if it prove inefficacious, antipyrine may be substituted. Sponging of the body may be resorted to in order to reduce a high temperature.

A comparison of the measures of management now generally pursued in this disease with the measures in vogue half a century ago shows a complete and radical change. Formerly, general and local bloodletting, cathartics, emetics, mercurials, counter-irritation, low diet, and confinement within doors were sanctioned by teachers and writers, and entered more or less into the treatment usually adopted. At the present time the measures which are most approved are, in all points, the reverse. The latter are based on more correct pathological views and the results of clinical observation. It is not unreasonable to hope that at some future time a remedy or remedies may be discovered capable of exerting a special influence over the disease, but in the mean time reliance is to be placed on an early diagnosis, the employment of remedies which, directly or indirectly, may exert, to a greater or less extent, a salutary influence, and, above all, on the hygienic measures which tend to

¹ Vide article by Dr. Robert Cheesman, in the *N. Y. Med. Record*, June 12, 1880.

² *Trans. Amer. Med. Assoc.*, 1880, p. 239.

invigorate and strengthen the system. The hygienic measures just referred to are to be enjoined with a view to the prevention of pulmonary phthisis. These measures are operative by affecting the conditions on which depends the tuberculous predisposition or diathesis. Prophylaxis is, of course, complete if the introduction of the infecting parasite can be prevented. As a measure for prevention a residence is desirable where there are few or no cases of phthisis. This effective precaution, however, is generally impracticable. Exposure to the infection should be restricted as far as practicable. Healthy persons should not occupy the same bed, and, except when required by the dictates of humanity, the same room at night, with tuberculous patients. Free ventilation of rooms occupied by patients should be enjoined. The sputa should be disinfected by carbolic acid or some other efficient agent. The flesh and milk of tuberculous cows have been shown to be capable of producing the disease; hence danger in this direction is to be avoided.

[SPECIFIC TREATMENT.—At the Tenth International Medical Congress, held at Berlin in 1890, Koch announced that he had discovered a substance capable of arresting the development of the bacillus tuberculosis in the bodies of animals. A few months later, the eagerly-expected remedy—the so-called lymph or tuberculin—was purchasable, and, the supply being naturally limited, the individuals who were so fortunate as to obtain the first samples congratulated themselves upon their commercial enterprise.

The substance was used in all the principal hospitals in this country, and it is now used in none. Nothing need be added to show the completeness of its failure to fulfil the expectations aroused by its announcement. If tuberculin were innocuous, it would doubtless still be employed, for there are many who still believe that it exerts a beneficial effect upon the course of tuberculosis, whether of lungs, joints, or skin. Unfortunately, however, its use is attended with danger. When administered in the manner and dose recommended by its discoverer, it is followed in four or five hours by violent febrile reaction, the rectal temperature sometimes rising to 105° F. or more, accompanied with vomiting, a sense of thoracic oppression, pains in the head and limbs, and delirium. On account of these and similar alarming symptoms, patients who had eagerly demanded a trial of the remedy have refused to submit to its repetition.

Notwithstanding its manifest dangers, physicians would be justified in urging their patients to submit to a thorough trial of tuberculin if it could be shown that its effect upon the local lesions is beneficial. Unfortunately, the reverse is the case. Examinations by Virchow of the bodies of those who had died while undergoing a course of treatment with tuberculin revealed recent acute inflammation in the neighborhood of old tubercular foci and an irruption of miliary granulations in the viscera and serous membranes. This report gave tuberculin its death-blow so far as its employment as a remedy for tuberculosis is concerned. It is now exclusively employed by veterinary surgeons as a test of the presence of tuberculosis in cattle. For this purpose it is of great practical value, since the febrile reaction and other symptoms above mentioned do not make their appearance unless the animal to which tuberculin is administered is tuberculous.

The principle upon which the treatment of pulmonary phthisis with tuberculin is based is undoubtedly correct. It is that pathogenic organisms secrete—or, rather, produce—substances (antitoxines) inimical to their own growth and development. This is universally recognized by experimental pathologists, and they are now searching for a substance, a modified form of tuberculin, containing the supposed curative virtues of the latter and free from its undoubted poisonous properties. It is too early to speak positively con-

cerning any of these substances. Suffice it to say that the best-known and most promising modifications of tuberculin are those of Hunter of England, Klebs of Germany, and Trudeau of the United States. The first named endeavors to free Koch's tuberculin of its toxic properties by dialysis; the second endeavors to accomplish the same object by precipitation with platinic chloride; while Trudeau has obtained excellent curative results in animals with soluble products contained in filtered culture-media.

The writer has employed Klebs' "tuberculocidin" at the Home for Consumptives at Chestnut Hill, Philadelphia, and can testify to its being absolutely innocuous and probably beneficial. He has also seen some of the animals experimented upon by Trudeau, and is convinced that his claim that "experimental tuberculosis in the rabbit's eye can be cured by injections of the filtered culture-medium" is fully warranted.

The reports from these and other experimenters serve to keep alive the hope that a specific for tuberculosis in man will yet be discovered.—H.]

CHAPTER VIII.

FIBROID PHTHISIS.—ACUTE MILIARY TUBERCULOSIS.— GENERAL TUBERCULOSIS.

Fibroid Phthisis.

THERE is no sharp line of demarcation between fibroid phthisis and other forms of chronic pulmonary phthisis from a pathological point of view; but in its typical manifestations, regarded from a clinical standpoint, it presents peculiarities sufficient to warrant separate consideration. In such typical cases the lung is shrunk in size, with a corresponding retraction of the chest-wall and often a lateral deviation of the spine. The external appearances are like those which follow chronic pleurisy. The pleura is much thickened by the development of firm connective tissue, and the pleural surfaces are adherent. In the substance of the lung there are firm, dense bands and masses or nodules of fibroid tissue, frequently deeply pigmented. Cheesy and calcareous masses are often lodged in the black or grayish indurated tissue. There are, as a rule, abundant and extensive bronchiectases. Ulcerative cavities may also be present. One lung is usually in a more advanced stage of the disease than the other. Usually, tuberculous granula are evident to the naked eye. The microscope shows the presence of tubercles, often of the most exquisite giant-celled type, in the lung. These undergo the fibroid metamorphosis to which reference has already been made. They are frequently situated in the bands of fibrous tissue. Tubercles with cheesy centres are also usually present. Some of the larger fibroid masses may present the tubercular tissue in a diffused form. In addition to the tubercles there is chronic inflammation of the interstitial tissue of the lung. The alveolar septa, the interlobular, and the peribronchial connective tissue become increased in amount. The air-cells and bronchi are compressed, and many of them obliterated. The new connective tissue may be rich in lymphoid cells, or the cells may be few in number and spindle-shaped. According to the amount of caseous or tuberculous pneumonitis present there exist all stages of transition between typical fibroid phthisis and the ordinary form of pulmonary phthisis.

The names chronic interstitial pneumonitis and cirrhosis of the lung (Crigan) have also been applied to this form of phthisis. The majority of cases of so-called fibroid phthisis are tuberculous, as has been described; at least some of the cases of chronic pulmonary inflammation resulting from the inhalation of fine foreign particles, such as bits of steel, of coal, etc. (kn grinder's, coaler's phthisis, etc.), seem to be examples of pure chronic bronchopneumonia and interstitial pneumonia.

This variety of phthisis is comparatively rare. In an exceedingly small proportion of cases it is preceded by acute pneumonitis; but in these cases the occurrence of the two diseases is probably due to coincidence. This may also be said of the cases in which it has been observed to follow bronchitis. In the majority of cases the age of patients is under forty years.

The local symptoms are cough with more or less expectoration, and want of breath on exercise. The sputum usually contains tubercle bacilli. The matter expectorated is often notably fetid, and sometimes suggestive of gangrene. Circumscribed gangrene occasionally occurs, but the fetor is generally due to the decomposition of muco-pus, from its detention in the cavities incident to bronchiectasis. Hæmoptysis, either slight or profuse, occurs in a considerable proportion of cases.

The disease may exist for an indefinite period without notable emaciation or debility; but sooner or later hectic paroxysms occur, diarrhœa is uncommon, the appetite fails, and there is of course a corresponding decrease of nutrition. The fingers often become clubbed. General dropsy occurs in a considerable proportion of cases. This is due to dilatation of the right side of the heart, an effect of the obstruction of the pulmonary circulation; and it is, assuming the absence of valvular cardiac lesions.

As regards physical signs, aside from the contraction of the chest there is more or less dullness on percussion, rarely flatness, and the resonance elicited is often tympanitic. The tympanitic quality is marked in proportion to the extent of bronchiectasis, which is a concomitant lesion, and of course it is most marked when the dilated bronchial tubes are free from morbid products. Saccular dilatations may occasion cracked-metal and amphoric resonance. Either ordinary cavernous or amphoric respiration may be heard in certain situations. In other situations the respiration may be bronchial or broncho-vesicular. In some situations the characters of cavernous and bronchial respiration may be combined. On the other hand, there may be absence of respiratory sound over more or less of the affected portions of the chest. The vocal signs: those denoting pulmonary solidification and cavities—namely, bronchophony, increased vocal resonance, and sometimes pectoriloquy. Bubbling and gurgling râles are often present. The dilatation of the right side of the heart may give rise to a tricuspid regurgitant murmur and to a jugular pulse. The shrinkage of the lung may cause considerable displacement of the heart. If the left lung be the seat of the affection, the heart is raised and carried to the left; if the right lung be affected, the heart is sometimes removed to the right side of the sternum.

As regards diagnosis, the ordinary form of phthisis is excluded by the extent of the damage, taken in connection with the fact that the affection is especially marked on one side, by the absence of the emaciation which generally characterizes the former, and by the long duration, often with little or no progress. This differential diagnosis is less easy when the affection is bilateral than when it is unilateral. Affections with which it may be confounded are chronic pleurisy and carcinoma. Chronic pleurisy, after the removal of effused liquid, does not furnish the signs of solidification, and perhaps the cavities, which belong to the clinical history of this disease. Carcinoma

the lung is generally secondary to carcinomatous disease in some other situation; the cancerous cachexia is often marked; there is progressive and perhaps rapid wasting of the body; and the progress of the disease is more rapid. The presence of the characteristic bacilli in the sputum is, of course, proof of the existence of tuberculous disease. In this variety of phthisis they are less abundant than in the ordinary form of the disease, and repeated examinations may be required for their discovery.

Fibroid phthisis involves lesions which do not admit of recovery. Sooner or later the disease ends fatally. But in many instances life is destroyed by some complication or an intercurrent affection. An acute pneumonitis affecting a lobe of the sound lung, or an attack of acute bronchitis, may prove fatal. The ability to resist any severe disease is, of course, impaired. Alone, the disease ends fatally by slowly-progressive exhaustion; but, existing alone, it may be tolerated for a great number of years.

The TREATMENT has for its most important object maintenance of nutrition and strength. The measures for this object are remedies to promote appetite and digestion, a nutritious and abundant alimenation, together with climatic and hygienic influences which tend to invigoration. Palliative measures, having reference to cough and expectoration, are indicated. Expectorants are useful by preventing the detention of muco-pus in the bronchial tubes, the decomposition of which increases the bronchial inflammation. The inhalation of the vapor of turpentine is useful. Antiseptic inhalations are indicated if the expectorated matter or the breath be fetid. [Pneumato-therapy has been much employed in the treatment of this disease, but may be productive of harm. The object of inhaling compressed or rarefied air is to dilate the contracted lung, but, unfortunately, such inhalations cannot be confined at will to any particular branch of the bronchial tree. They penetrate in the direction of least resistance—*i. e.* toward the comparatively sound lung, which may be already in a state of vicarious emphysema.—H.]

Acute Miliary Tuberculosis—General Tuberculosis.

Acute miliary tuberculosis is characterized by the presence of miliary tubercles in most of the organs of the body. It is caused by the entrance of tubercle bacilli into the blood-current and their transportation to most parts of the body.

The organs almost constantly affected are the lungs, the liver, the spleen, and the medulla of the bones, and with nearly equal frequency the kidneys, the thyroid gland, the heart, the choroid coat of the eye, the lymph-glands, and the serous membranes. The affected organs are usually studded with small, grayish, firm nodules, which present the tuberculous structure already described in the article on Pulmonary Phthisis. Some of the tubercles, particularly those in the liver, are so small that they can be seen only with the microscope. The longer the duration of the case, the larger are the tubercles and the more extensive the cheesy degeneration of their centres. The lungs are hyperæmic, and the air-cells contain a small, rarely a large, amount of desquamated epithelium and of inflammatory products, particularly in the neighborhood of the tubercles. Acute inflammation of the bronchial mucous membrane coexists. More or less enlargement of the spleen is usually present. Certain peculiarities in the structure and the distribution of the tubercles in particular organs will be subsequently mentioned in connection with tuberculous disease of these organs. All tubercles, at least at the beginning of their formation, contain bacilli. The bacilli may be very few and difficult to find.

In most but not in all cases it is possible to demonstrate at the autopsy or by subsequent microscopical examination the mode in which the tubercle bacilli gain access to the blood-current. The mode of infection varies in different cases. It is usually to be found in some old tuberculous focus which may or may not have given rise to symptoms during life. In many cases tuberculous nodule or mass has ruptured into one of the veins, particularly into one of the pulmonary veins. A frequent instance of this is the bursting of a caseous bronchial gland into a pulmonary vein. In some cases the general infection has occurred from tuberculosis of the thoracic duct or from rupture of tuberculous material into the duct. The seat of entrance of the bacilli into the blood may be demonstrable only by microscopical examination; but then the chances of discovering it are much less than in the instances which have been mentioned. It is hardly necessary to say that the idea once entertained that any indifferent cheesy mass in the body might be the source of general tuberculous infection is not true. The primary cheesy mass must be of tuberculous origin in order to cause general tuberculosis.

As has already been mentioned, the focus of local tuberculosis—which in most if not in all cases antedates the general tuberculosis—may or may not have given rise to characteristic symptoms. All varieties of local tuberculosis such as pulmonary tuberculosis, tuberculous disease of the bones and of the joints, genito-urinary tuberculosis, and tuberculosis of the lymphatic glands may be followed by acute miliary tuberculosis.

In some cases it is impossible to find any tuberculous products which seem to date the general tuberculous infection. Whether in these cases the primary tuberculosis is overlooked, or whether in rare instances in some undefined way tubercle bacilli may directly invade the blood in large numbers without it is uncertain. Acute miliary tuberculosis frequently develops in persons apparently in perfect health. It does not often develop in the course of pulmonary phthisis.

In cases of acute miliary tuberculosis tubercle bacilli have been found in the blood both during life and at the autopsy. They have been found in blood withdrawn during life from the spleen by a hypodermic syringe.

With reference to the symptomatology and diagnosis, it is to be noted that acute miliary tuberculosis is limited to cases in which tubercle bacilli invade a single organ, such as the lungs, the pia mater, or the genital system, or invade a large number of organs. The lungs may be predominantly affected, but tubercles exist also in other parts.

Acute miliary tuberculosis are rare; they occur mostly after puberty and before middle age, but no age is exempt from a liability to the disease. The symptoms denote a febrile disease. The temperature of the body is usually elevated, but there is much variation in this regard in different cases. There is sometimes hyperpyrexia. Variations in the pyrexia in the course of the same case are sometimes marked. The pulse is usually rapid, ranging from 120 to 140 per minute. There is complete anorexia, and the thirst is great.

Sputum is usually notably frequent, from 30 to 60 per minute, and is usually scanty. The expectoration varies, and is sometimes purulent, sometimes bloody. Tubercle bacilli have been found in the sputum, but this is not always the case. The expectoration proceeds from secondary bronchitis, and is usually scanty. Hemoptysis is an occasional event. Anomalous cases, such as may well be seen in *Phthisis* is one in which the disease be-

gins in the lungs, and spreads to the bronchial lymphatic glands by enormous numbers of tubercle bacilli. See *Archiv. f. Klin. Med.*, Bd. 102, p. 397, in which case the disease was fatal.

with a profuse hæmoptysis. Another instance has more recently come under my observation. In some instances there is much suffering from dyspnœa, but patients do not always complain of a sense of the want of breath even when the respirations are notably hurried. Cyanosis is often a prominent symptom. Double pleurisy with effusion occurs in some instances.

The shortest duration in the cases which I have observed was eleven days. It rarely exceeds two months. Although there is great interference with the respiratory function, asthenia predominates in the mode of dying.

The disease may have no distinctive physical signs. If tubercles be disseminated about equally in both lungs, they do not occasion an appreciable dulness on percussion or the auscultatory signs of solidification. Some dry and moist bronchial râles, due to bronchitis, may be heard at different points, but these are not constant. The fact that physical exploration gives a negative result is to be taken into account in the diagnosis. This result excludes other pulmonary diseases which might give rise to the pulmonary symptoms—namely, lobar pneumonia, the common form of pulmonary phthisis, and capillary bronchitis. The basis of the diagnosis is the exclusion of these affections and the fact that the symptoms point to some grave intrathoracic and general disease.

The difficulty in the diagnosis relates chiefly to the differentiation from typhoid or typho-malarial fever. With these diseases acute miliary tuberculosis is apt to be confounded. This error is likely to be made if, as sometimes happens, cough with expectoration, rapid breathing, dyspnœa, and cyanosis are not as prominent as they are in the majority of cases. Moreover, in some cases of acute miliary tuberculosis fever heat ceases in the course of the disease. Typhoid and typho-malarial fever are to be excluded by the absence of the diagnostic characters of these affections. Positive proof of the existence of tuberculosis is obtained, of course, if examinations of the sputum show the presence of the bacillus tuberculosis. This proof, however, may not be obtained in cases of miliary tuberculosis. There are not as yet sufficient observations to determine how frequently tubercle bacilli may be found in the blood during life in case of acute miliary tuberculosis. The recognition by the ophthalmoscope of tubercles in the choroid coat of the eye may render great assistance in diagnosis.

The TREATMENT of acute miliary tuberculosis may be dismissed with a very few words. The condition of the patient is hopeless, and all that the physician can do is to palliate symptoms and sustain the powers of life. This is one of the diseases in relation to which recovery is proof of an error in diagnosis.

ingress of the inspired air into the air-cells, without obstructing the egress of air from the cells in expiration; hence collapse occurs of the lobules to which the obstructed tubes are distributed. In expiration the plugs are moved by the current of air from the smaller into the larger tubes, but in inspiration the current moves them into a position in which the progress of air is interrupted. It is supposed that collapse may occur when the current of air in expiration as well as in the act of inspiration is obstructed, the air which is thus pent up in the lobules being absorbed. In proportion to the number of collapsed lobules the respiratory function is compromised, and danger from apnoea may attend this accident. It is more liable to occur in young children than in adults, because children do not promote expectoration by voluntary efforts, and also because the respiratory acts are less vigorous. It occurs especially in feeble children. It does not, however, belong exclusively to acute bronchitis in young children; it occurs in aged persons, and may take place in those of any age who are constitutionally weak. It is also incidental to chronic bronchitis in children and adults, and it enters, as will be seen hereafter, into the causation of emphysema of the lungs.

The occurrence of collapse of pulmonary lobules may be strongly suspected in the course of acute bronchitis if the respirations become frequent, with dilatation of the *alæ nasi*, accompanied perhaps with lividity, and if the symptoms and signs of acute lobar pneumonitis be wanting. Physical exploration does not always furnish definite signs of this accident. Relative dullness on percussion may be found on one side if there be a marked disparity between the two lungs as regards the number of lobules which are collapsed. The respiratory murmur is more feeble over the posterior than over the anterior portion of the chest, and if relative dullness on percussion exist on one side the murmur of respiration will be more feeble on that side. Mucous râles are more or less abundant.

In the TREATMENT of bronchitis in young children the liability to this accident is to be considered. Mild emetics are indicated with a view to promote the expulsion of mucus from the bronchial tubes. They are admissible because they occasion less disturbance than in adults. They are indicated because in young children the acts of coughing are for the most part purely reflex; that is, voluntary efforts to expectorate are not made. They should not, however, be repeated too frequently, and antimonial emetics should never be employed. Apomorphia, administered hypodermically, has been recommended as an emetic and expectorant; but the grave effects which have sometimes followed small doses render the use of this remedy of doubtful expediency, especially in young children. Remedies to maintain nausea are contraindicated on account of their depressing effect; an emetic should be given to produce prompt vomiting, and afterward nauseant remedies withheld until a repetition of the emetic be deemed advisable. In the interval, tonic remedies, a nutritious diet, and perhaps alcohol, are called for to support the general strength. Opium is to be given with great circumspection, since it may favor the accumulation of mucus in the bronchial tubes. The chief objects of treatment, in short, are twofold: *first*, to supply the want of voluntary efforts of expectoration by the judicious employment of emetics; and *second*, by sustaining measures to maintain the force of the respiratory acts. The iodide of potassium, given pretty freely, has seemed to me to have a curative effect. Measures to excite deep inspirations, referred to in connection with broncho-pneumonitis (vide p. 92), are to be mentioned as entering into the treatment.

tion, and collections of round cells may be detected in the peribronchial connective tissue.—H.] Sometimes, especially in the early stage of the disease, the product is chiefly mucus, when it appears translucent and viscid; at other times it is yellowish, when it contains abundant pus-cells. A coating of muco-pus is found upon the inflamed mucous membrane after death.

In ordinary bronchitis the inflammation, as already stated, is limited to the large bronchial tubes. The tubes on both sides are equally affected, provided the affection be not incident to an antecedent pulmonary disease. With this exception, bronchitis exemplifies the law of parallelism; it is a bilateral or symmetrical disease. In this respect it differs from pleuritis and lobar pneumonitis.

CLINICAL HISTORY.—Acute bronchitis is generally preceded by inflammation of the mucous membrane of the nasal passages, or coryza. The inflammation begins in the nostrils and travels downward, either affecting or passing by the pharynx and larynx in its passage to the bronchial tubes. The period occupied in the passage varies from a few hours to one, two, or three days. In a certain proportion of cases the bronchial tubes are attacked at once without any affection of the air-passages above.

The symptoms offer marked points of contrast with acute pleuritis and pneumonitis. Pain is not a prominent symptom, but the patient has a sense of constriction and of soreness or rawness. These painful sensations especially accompany acts of coughing. The pain is of an obtuse or contusive character, and is situated beneath the sternum.

The attack is rarely accompanied by a distinct chill, but chilly sensations, followed by flashes of heat, are frequently repeated during the career of the disease. The appetite may be more or less impaired, but is not usually lost. Lassitude is complained of, with a general feeling of malaise.

The pyrexia is moderate. The pulse has not the frequency and strength which it has in pleuritis and pneumonitis. The heat of the surface is not notably raised.

The cough is at first painful, but not sufficiently so to be suppressed. It is at first dry, the secretion of mucus being for a time scanty. Deep inspirations, breathing cold air, and the exercise of the voice excite acts of coughing, which occur in paroxysms and consist of a deep inspiration followed by a series of expiratory efforts. If the paroxysms of coughing be frequent and severe, the traction of the diaphragm occasions pain and soreness, referred to the false ribs and the ensiform cartilage. The patient feels as if a more abundant expectoration would give relief, and desires to have the cough loosened. The expectoration is at first small, glairy, frothy, and viscid, and occasionally streaked with blood. In the progress of the disease, after two, three, or four days the expectoration becomes more abundant, and consists of thick, yellowish, or greenish sputa. The cough is then said to be loose, the acts of expectoration being easier, unattended by pain or soreness, and followed by a sense of comfort. The mucous secretion is rarely sufficient to accumulate in the tubes and occasion embarrassment of respiration. This may happen, however, in young children, in the aged, in feeble persons, and in patients with paralysis affecting either the diaphragm or the costal muscles. The presence of a collection of mucus in the large bronchi or trachea is felt, and the patient is led to make voluntary efforts of coughing for its expulsion. The increased amount of the inflammatory products and the change in character denote diminution or resolution of the inflammation.

Respiration is not sensibly affected. No portion of the lung is withdrawn from the exercise of its function, as in pleurisy and pneumonitis. Dyspnoea is not produced, save in the exceptional cases in which, from feebleness or the

want of voluntary efforts of coughing, the mucous secretions accumulate sufficiently to obstruct the bronchial tubes, provided the bronchitis be not super-added to emphysema or some other pulmonary affection and the muscles of respiration be not paralyzed.

The affection is not accompanied by much debility. Patients are generally not confined to the bed, and they may not confine themselves to the house.

The average duration of acute bronchitis is ten or twelve days. In severe cases after five or six days patients are usually able to be out of doors.

The disease may be divided into two stages. The first stage embraces the period during which the expectoration is scanty, transparent, and viscid. The second stage extends from the time when the expectoration becomes abundant, opaque, and thick, to convalescence.

PATHOLOGICAL CHARACTER.—Acute simple bronchitis is an inflammation affecting a mucous membrane, leading to a secretion of mucus and the production of muco-pus in greater or less abundance. Resolution takes place in the bronchial membrane without the occurrence of ulcerations.

CAUSATION.—Primary or idiopathic bronchitis is attributed to the agency of cold. This is implied in the designation by which the affection is popularly known—namely, “a cold.” Exposure to cold is supposed to produce this disease by interrupting the eliminative functions of the skin, whereby an increased duty is thrown upon the pulmonary mucous membrane, and by inducing internal congestion. This view of the causation is inconsistent with the fact that great exposure, in a large proportion of cases, is not followed by bronchitis, and also with the fact that in many cases bronchitis is not traceable to any unusual exposure. It is reasonable to conclude that the disease is due to a morbid agent in the atmosphere. This is of course to be inferred when the disease prevails as an epidemic; but it is a matter of common observation that a greater or less number of persons are likely to be simultaneously affected when the number is not enough to constitute an epidemic. That the special morbid agent is a micro-organism—in other words, that the disease is parasitic—is rendered probable by the absence of any appreciable causation in a large proportion of cases, and by the fact that the bronchial inflammation is preceded in most cases by coryza, frequently by laryngitis, and sometimes by pharyngitis, these affections successively occurring after intervals of several hours or days. It seems rational to attribute these successive affections to the migration of the parasites downward, and the formation of colonies in the parts successively affected.¹ The disease is more frequent in cold and temperate latitudes than in the tropics; and in the former it prevails especially in the spring and autumnal months. It presents a contrast to acute lobar pneumonitis, which occurs oftener in warm than in cold climates.

Bronchitis occurs secondarily to, and forms an element of, other diseases. It belongs to the clinical history of rubeola, or measles. In connection with this disease it is frequently acute. It occurs in typhoid fever, but is rarely acute in connection with that disease. Developed in connection with diseases situated elsewhere than in the pulmonary organs, it is symmetrical, as when it occurs primarily; but, developed as a complication of pneumonitis and phthisis, it may be limited to one side—that is, unilateral—and is confined within a circumscribed area.

It may be produced traumatically by irritating gases received with the inspired breath. Inhalation of chlorine gas will produce it. I have known

¹ Vide “Suggestions as to the Etiology, etc. of Acute Coryza,” by the author in *Journal of the American Medical Association*, Nov. 14, 1885.

a severe attack produced by inhaling the fumes of sulphuric acid. In some persons, owing to an idiosyncrasy, the bronchial membrane becomes inflamed by constituents of inspired air which are innocuous when inhaled by most persons. The powder of ipecacuanha, emanations from newly-mown hay and from feathers, the pollen of certain plants in the atmosphere during the summer and a portion of the autumnal season, and even fragrant odors, will produce bronchitis in those having a peculiar susceptibility to these causes. Frequently in these cases to the bronchitis is added asthma; and this idiosyncrasy will be noticed in connection with the latter affection. (Vide Chapter X.)

As a rule, the liability to bronchitis is less in proportion as persons are habituated to free exposure in the open air. It is much more liable to attack persons who spend most of their time in warm apartments than those whose occupations keep them out of doors. Soldiers, surveyors, explorers, and hunters, who are accustomed to sleep at night in tents or in the open air, rarely "take cold," but it is a matter of frequent observation that after having been for some time accustomed to camping out of doors bronchitis occurs on resuming in-door quarters. If the parasitic doctrine be admitted, these facts point to the importance of peculiar local conditions favorable to the multiplication of the parasite.

DIAGNOSIS.—Acute bronchitis is to be discriminated from pleuritis and acute lobar pneumonitis, more especially the latter. The points relating to symptoms which are involved in this differential diagnosis are as follows: the absence of lancinating pain, the pain which is felt being subternal; the presence of more or less expectoration which is not rusty, but either devoid of blood or containing it in the form of streaks; absence of accelerated breathing and dyspnoea; absence of the circumscribed flush of the cheeks; and the pre-existence of coryza, with, perhaps, soreness of the throat, and subacute laryngitis. These points are chiefly negative, and they are not sufficient for a positive diagnosis in all cases, because the symptoms belonging to pleuritis or pneumonitis, which are wanting in bronchitis, are not uniformly present in cases of the two former diseases. The clinical history, however, and the results of physical exploration render the diagnosis easy and positive.

The physical diagnosis is based chiefly on negative points. Percussion elicits the resonance of health. The vocal resonance is unaffected. The respiratory murmur may be weakened, but is not otherwise altered. Suppression of the murmur over a portion of the chest may occur temporarily from obstruction of a bronchial tube by an accumulation of mucus. These negative points warrant the exclusion of pleuritis and pneumonitis. The dry and moist bronchial râles may or may not be present at the time when the explorations are made. Their presence and diffusion more or less over both sides are indicative of the existence of the disease, but the absence of the disease is not to be inferred because these signs are wanting when the chest is examined. They are oftener wanting than present, the conditions giving rise to the dry râles not existing, and the mucus in the bronchial tubes being too adhesive or thick to produce bubbling sounds.

PROGNOSIS.—Acute ordinary bronchitis, not associated with other affections, is a dangerous disease only when it occurs in the young, the aged, or the feeble. The danger in these classes of patients arises from the accumulation of the products of inflammation within the bronchial tubes, and from the occurrence of collapse of pulmonary lobules or broncho-pneumonia. The danger relates to apnoea. The disease does not lead to great prostration and

danger from asthenia. Exclusive of the classes of patients just named, it is generally a disease of little or no gravity. In the great majority of cases it passes through its course and the recovery is complete, but it may eventuate in chronic bronchitis. Associated with certain other affections, it may give rise to much suffering and danger. Occurring, for example, in patients affected with pulmonary emphysema, it occasions more or less dyspnoea, and it may prove fatal if the amount of emphysema be great. So in cases of spinal paralysis affecting the costal respiratory movements the accumulation of the bronchial secretions, from inability to expel them by the action of the diaphragm, alone may occasion death by slow apnoea.

The disease has no tendency to induce either pleuritis or acute lobar pneumonia, and, contrary to a general impression, it rarely precedes the development of pulmonary phthisis.

TREATMENT.—Acute bronchitis may be prevented in some instances, on the appearance of coryza, by a full opiate. A quarter of a grain of the sulphate of morphia, half a grain or a grain of codeia, a proportionate dose of any of the preparations of opium, or ten grains of either Dover's or Tully's powder, may be given to an adult for this object at bedtime, accompanied by a hot pediluvium and some warm stimulating drink, such as weak punch or toddy or an infusion of some of the aromatic herbs, and followed in the morning by a saline purgative. If this plan of treatment do not succeed, it may mitigate the severity of the disease. A full dose of a salt of quinia (a scruple to an adult) will often act as a prophylactic, or, if given at once when the bronchial tubes become affected, as an abortive remedy. Twenty grains of salicin, repeated once or twice after an interval of two hours, will be likely to prevent or arrest the disease. The Russian or Turkish bath is sometimes effective.

If it be true that the efficient cause is a parasitic organism, topical treatment for its destruction is a rational object of prophylactic treatment. Destruction of the parasite in the nostrils of course prevents the migration and colonization in the parts below. Certain topical applications within the nostrils have been found efficacious. One of these is the German remedy, known as the Brandt-Hagen remedy, consisting of carbolic acid 80 grains, alcohol $\frac{1}{2}$ ounce, liquor ammoniæ 80 minims, and distilled water 2 $\frac{1}{2}$ drachms. This liquid is poured upon a sponge placed within a paper cone, and the vapor inhaled through the nostrils. Camphor and quinia in equal parts combined, pulverized, and inhaled, is a popular remedy said to be efficacious.

If the disease become established, it does not claim active measures of treatment in view of the almost uniform tendency to recovery with mere attention to hygiene. Bloodletting is not called for except in some rare cases in which the patient is full-blooded and the symptomatic fever unusually intense. Depletion by means of saline laxatives and reduced diet will generally suffice. If the attack be severe, confinement to the bed for a few days may be advisable in order to secure uniform warmth and moisture of the surface. Patients are more comfortable when moderately perspiring. In severe cases an abundance of moisture in the apartment soothes the inflamed membrane and renders the patient more comfortable.

Opium is thought by many to be contraindicated in the first stage. It is supposed to interfere with the free secretion of mucus and to render expectoration difficult. This is an inference from the effect of opium on the secretions in health; but, so far from these results being produced, opium hastens the second stage. The free secretion of mucus is not the cause, but the consequence, of an abatement of the inflammation, and by contributing to the latter opium virtually acts as an expectorant. Opium, therefore, is indicated

There are no symptoms or signs by means of which the diagnosis of this variety of bronchitis can be made out prior to the expectoration of false membrane or bronchial casts. When this occurs the character of the affection is of course manifest. This expectoration is preceded and accompanied by violent paroxysms of coughing. It is followed by a muco-purulent expectoration, which may be bloody. The symptoms are relieved by the removal of the fibrinous exudations or casts. The expectoration of the latter may be repeated after intervals of days, weeks, months, or even years. The character of the disease, if it prove fatal before the expectoration of false membrane takes place, may be suspected, but the symptoms and signs show only the existence of bronchitis with obstruction of bronchial tubes and perhaps collapse of pulmonary lobules. This variety of bronchitis sometimes recurs repeatedly in the same person. I have met with cases in which a large number of bronchial casts (forty or fifty) were expectorated at as many different times.

The principles of treatment are essentially the same as in cases of acute or chronic bronchitis without this peculiar feature, and they need not be separately considered. Warm vapors or sprays inhaled will aid in the separation of the false membrane, [and they may be medicated with carbonate of sodium or potassium (1 per cent.), both of these substances being solvents of fibrin. Pilocarpine has been suggested as a remedy likely to prove effective in these cases, on account of its property of producing a copious liquid secretion from the bronchial mucous membrane. Mercury and potassium iodide have been administered with the object of preventing a return of the paroxysms, and with apparent success. If possible, the winters should be spent in a climate, such as the sea-coast of Florida, where the air is both warm and moist.—H.]

Circumscribed Bronchitis.

As already stated, bronchitis when circumscribed is incidental to some other pulmonary disease. It is developed in pneumonitis, being limited to the lobe or lobes affected, and is the chief source of the expectoration in this disease if it do not go on to the suppurative stage. It occurs in pulmonary phthisis, and is limited to the tubes in proximity to the seat of the deposit of tubercle. The bronchitis in this disease furnishes the expectoration prior to the softening and discharge of the tuberculous product. As thus developed, bronchitis claims no special attention in a therapeutical point of view.

Chronic Bronchitis—Fetid Bronchitis.

Chronic bronchitis may follow the acute form or it may be subacute from the beginning. It is far less frequent than acute bronchitis. It occurs much oftener in aged persons than during the early and the middle period of life. It is associated with asthma, pulmonary emphysema, and cardiac lesions, especially those involving mitral stenosis or incompetence of the mitral valve, [and is not infrequently a manifestation of some underlying constitutional condition such as gout, rheumatism, or renal disease.—H.]

The hyperæmia is less intense than in acute bronchitis. The color of the mucous membrane may be bluish-red or it may be grayish or slate-colored. The morbid products upon the membrane are similar to those in acute bronchitis, but usually with greater predominance of mucus. More extensive changes, however, may occur in the bronchial wall. This, on the one hand, may become thickened by the development of new connective tissue, or it may become thinned in consequence of atrophy of the connective tissue and

ingress of the inspired air into the air-cells, without obstructing the egress of air from the cells in expiration; hence collapse occurs of the lobules to which the obstructed tubes are distributed. In expiration the plugs are moved by the current of air from the smaller into the larger tubes, but in inspiration the current moves them into a position in which the progress of air is interrupted. It is supposed that collapse may occur when the current of air in expiration as well as in the act of inspiration is obstructed, the air which is thus pent up in the lobules being absorbed. In proportion to the number of collapsed lobules the respiratory function is compromised, and danger from apnoea may attend this accident. It is more liable to occur in young children than in adults, because children do not promote expectoration by voluntary efforts, and also because the respiratory acts are less vigorous. It occurs especially in feeble children. It does not, however, belong exclusively to acute bronchitis in young children; it occurs in aged persons, and may take place in those of any age who are constitutionally weak. It is also incidental to chronic bronchitis in children and adults, and it enters, as will be seen hereafter, into the causation of emphysema of the lungs.

The occurrence of collapse of pulmonary lobules may be strongly suspected in the course of acute bronchitis if the respirations become frequent, with dilatation of the *alæ nasi*, accompanied perhaps with lividity, and if the symptoms and signs of acute lobar pneumonitis be wanting. Physical exploration does not always furnish definite signs of this accident. Relative dullness on percussion may be found on one side if there be a marked disparity between the two lungs as regards the number of lobules which are collapsed. The respiratory murmur is more feeble over the posterior than over the anterior portion of the chest, and if relative dullness on percussion exist on one side the murmur of respiration will be more feeble on that side. Mucous râles are more or less abundant.

In the TREATMENT of bronchitis in young children the liability to this accident is to be considered. Mild emetics are indicated with a view to promote the expulsion of mucus from the bronchial tubes. They are admissible because they occasion less disturbance than in adults. They are indicated because in young children the acts of coughing are for the most part purely reflex; that is, voluntary efforts to expectorate are not made. They should not, however, be repeated too frequently, and antimonial emetics should never be employed. Apomorphia, administered hypodermically, has been recommended as an emetic and expectorant; but the grave effects which have some times followed small doses render the use of this remedy of doubtful expediency, especially in young children. Remedies to maintain nausea are contraindicated on account of their depressing effect; an emetic should be given to produce prompt vomiting, and afterward nauseant remedies withheld until a repetition of the emetic be deemed advisable. In the interval, tonic remedies, a nutritious diet, and perhaps alcohol, are called for to support the general strength. Opium is to be given with great circumspection, since it may favor the accumulation of mucus in the bronchial tubes. The chief objects of treatment, in short, are twofold: *first*, to supply the want of voluntary efforts of expectoration by the judicious employment of emetics; and *second*, by sustaining measures to maintain the force of the respiratory acts. The iodide of potassium, given pretty freely, has seemed to me to have a curative effect. Measures to excite deep inspirations, referred to in connection with broncho-pneumonitis (*vide p. 92*), are to be mentioned as entering into the treatment.

Acute Bronchitis affecting the Small Bronchial Tubes.

An extension of inflammation from the larger and medium-sized tubes to those of small size gives rise to the variety of bronchitis commonly called capillary bronchitis. This application of the term capillary is not strictly correct. The truly capillary tubes—that is, the ultimate subdivisions of the bronchial tree, or the bronchioles—are not the seat of inflammation in this affection. They are involved in pneumonitis. The bronchial branches of small size, but not the smallest, are affected in so-called capillary bronchitis. The larger tubes are generally first affected, and the small tubes become involved by a more or less rapid extension of the inflammation. The affection has heretofore been known by various titles, such as catarrhus senilis, peripneumonia notha, bastard pleurisy, suffocative catarrh, etc.

This affection differs widely from ordinary acute bronchitis as regards its clinical history and danger. It is an exceedingly grave affection, proving fatal, especially in young children, in a large majority of cases. The danger proceeds from obstruction to the current of air to and from the air-vesicles. The obstruction is due to the small size of the affected tubes; the swelling of the mucous membrane and the presence of muco-purulent liquid, which in the larger tubes do not interrupt the free passage of air, occasion in the small tubes serious interference, and, as the affection is bilateral, fatal apnoea is liable to be produced.

In acute bronchitis of the small bronchial tubes the inflammation is much more intense than in acute simple bronchitis of the large tubes. The small bronchi contain muco-pus, which escapes in small drops when a section of the lungs is made. Upon microscopical examination the walls of the affected portions of the bronchi are found infiltrated with emigrated white blood-corpuscles, and frequently inflammatory products exist in the air-cells immediately adjacent to the inflamed bronchi. Obstruction from plugging of the tubes with muco-pus leads to collapse of pulmonary lobules. These collapsed lobules become secondarily inflamed. It is thus seen that the lesions are not confined to a simple inflammation of the mucous membrane of the small bronchi, but embrace also inflammation of the other coats of the bronchi and of the air-cells in connection with the bronchi. There is, therefore, in most cases, broncho-pneumonitis. The lungs are generally hyperæmic, and are often œdematous. There is usually compensatory emphysema of the superior and anterior parts of the lungs.

The mechanical obstruction and the incidental circumstances just stated afford an explanation of the symptoms which make up the clinical history of this variety of bronchitis; and as regards its clinical history it presents a striking contrast to acute bronchitis limited to the larger tubes. The respirations are frequent in proportion to the bronchial obstruction. In young children they may be increased to 60 or 70 per minute. Dyspnoea exists in a degree corresponding to the acceleration of breathing. In severe cases it amounts to orthopnoea, the patient keeping the sitting posture and suffering extremely for the want of breath. The speech is short and jerking; the alæ nasi dilate; the face is congested and swollen; and the countenance expresses anxiety and distress. Lividity is marked, partly in consequence of imperfect oxygenation of the blood, but more especially of its accumulation in the right cavities of the heart (cyanosis). There is great restlessness. The pulse is notably frequent, but not accelerated in proportion to the respirations. Cough is more or less prominent, and is difficult and ineffectual from the want of breath. The expectorated matter coming from the small tubes does not contain bubbles of air; its specific gravity is greater than that of water, and it has sufficient consistence to preserve the form of the tubes. In its passage

along the large tubes it becomes mixed with mucus from the latter, which contains air and consequently floats on water. The characteristic expectoration consists of mucus floating on water, with which are connected filaments sinking below the surface.

The symptoms distinguish sufficiently capillary bronchitis from bronchitis limited to the larger tubes, but they do not always suffice for the discrimination of this from other affections. It should never be confounded with laryngeal affections occasioning obstruction (simple or pseudo-membranous laryngitis), for in these affections the voice is affected, the cough is characteristic, and the respirations are labored, but not notably accelerated. Attention to the points just named will show the affection to be seated within the chest. The diseases with which it is most liable to be confounded are pneumonia, asthma, and ordinary acute bronchitis with collapsed lobules. It may generally be discriminated from these affections by means of physical signs taken in connection with the symptoms. The resonance on percussion is diminished in capillary bronchitis, and over the upper lobes it may be greater than in health, owing to an emphysematous condition of the air-vesicles. The presence of muco-purulent liquid in the small tubes gives rise to fine bubbling (subcrepitant) râles. As the affection is bilateral, the râles are heard on both sides, and especially on the posterior aspect of the chest. The respiratory murmur is weakened. The anterior, superior, and middle portions of the chest in a young child may become largely dilated, presenting the characteristic deformity of long-continued and great emphysema, this appearance appearing after recovery.

Lobar pneumonia is to be excluded by the absence of the symptoms and signs diagnostic of that disease. Dulness on percussion extending over one or more lobes is wanting. Pneumonitis is generally abruptly developed, is not preceded or accompanied by bilateral bronchitis. It is rare for pneumonia affecting but one lobe to occasion so much disturbance of the respiration as takes place in severe cases of capillary bronchitis. The crepitant râle, if it be present, denotes pneumonia, and if this affection exist and be advanced far enough for bubbling râles to become developed, the latter are confined to one side only, except in the rare instances in which the pneumonia is double. The temperature of the body is, as a rule, higher than in capillary bronchitis, the thermometer in the latter rarely showing an elevation above 102° F.

Asthma is not accompanied by pyrexia. The respirations are not rapid but labored, the labor being especially marked in expiration (expiratory dyspnoea). They are accompanied by loud sibilant and sonorous râles. It is a paroxysmal affection, the dyspnoea not persisting as in capillary bronchitis; and unless the case happen to be one in which asthma is experienced for the first time, the liability of the patient to this affection is known.

The discrimination from acute bronchitis of the larger tubes with collapsed lobules or broncho-pneumonitis is more difficult. The differential diagnosis must be based on the greater gravity of the symptoms, the clearness of the resonance on percussion, and the diffusion over both sides of the subcrepitant râles in cases of capillary bronchitis.

Extensive broncho-pneumonitis supervening upon capillary bronchitis increases the gravity of the local symptoms and the danger. A rise of temperature to 103° or 104° renders this complication probable, but by no means certain, for, exceptionally, these temperatures are observed in cases of capillary bronchitis without the pneumonic complication. The occurrence of the latter cannot always be ascertained by means of physical signs.

Pleuritis with large effusion may give rise to accelerated breathing, liv-

ity, etc., but this affection is readily excluded by the absence of the signs denoting the accumulation of liquid in the pleural cavity.

(Capillary bronchitis occurs especially in young children, and next in frequency in the aged, but it is occasionally met with in adults. It is always a disease of gravity, but particularly so at the two extremes of life. In young children and the aged it proves fatal in a very large proportion of cases. It destroys life in some cases rapidly. I have known it to prove fatal in less than twelve hours after the symptoms denoted gravity of disease. The average duration in fatal cases in children is from three to five days. The duration is longer in adults, and the disease is much less grave after childhood and during middle age. In cases ending in recovery, convalescence becomes established after a duration varying from a week to two weeks. Happily, it is by no means a disease of frequent occurrence even in young children. In the mode of dying apnoea predominates; and the progress toward a fatal termination is denoted by increasing lividity, the pulse becoming more and more frequent and feeble, the skin covered with clammy perspiration, the labor and frequency of the respirations, together with cough and expectoration, diminishing toward the close of life from muscular prostration. Thrombosis, or the formation of a clot in the right side of the heart, is an occasional accident which may prove the immediate cause of death.

TREATMENT.—Bloodletting may be employed at the onset under those conditions by which the employment of this remedy in other inflammatory affections is to be regulated. It is not admissible in young or feeble subjects, and in employing this or any other debilitating measure the physician should not lose sight of the fact that it is important to economize the strength of the patient in order that the laborious efforts of breathing may be carried on for a length of time sufficient for the resolution of the disease. The danger and distress incident to the disease arise chiefly from the deficiency of fresh supplies of air in the air-cells; and if bloodletting be injudiciously practised, the patient suffers from the want of both blood and air. The importance of economizing strength should also enforce circumspection in the use of saline depletants and sedative remedies. These should not be pushed to the extent of producing prostration. The difficulty consists in mechanical obstruction, which neither these nor any therapeutical measures will immediately remove. The safety of the patient depends on the maintenance of life until the disease passes through its career. The inhalation of oxygen affords marked relief of the dyspnoea. Breathing warm vapor is not only highly useful as a palliative measure, but it does not a little toward promoting resolution of the inflammation. It should form an important part of the treatment; and the most effective method is to keep the atmosphere of the room constantly and abundantly charged with steam during the course of the disease. Water in several vessels should be kept at the point of ebullition by means of heat in fireplaces, stoves, or burning gas. [Steam should also be occasionally inhaled directly from an atomizer. It is probable that medicated sprays are more efficacious than those of simple water, and the best solutions for this purpose are chloride of sodium and carbonate of sodium, of the strength of from 1 to 5 per cent.—H.] The temperature of the room should be kept at a high point, 85° to 90°. The iodide of potassium should be given freely.

Emetics in young children are advisable for a reason already stated—namely, to supply the want of voluntary efforts of expectoration. Care, however, is to be taken not to repeat them so often as to occasion exhaustion. The use of apomorphia has been already referred to (p. 144). Laxatives are useful by diminishing the contents of the intestines, and thereby

giving space for more effective action of the diaphragm in respiration. [Irritative applications to the chest are useful, but blisters are of doubtful value. Warm baths followed by cold sponging are useful both for their general and local effects. They are tranquillizing to the nervous system, and, by promoting more active respiratory movements which they excite, promote expectoration and prevent collapse of the lung.—H.]

The great object being to carry the patient safely through the disease, supporting measures are early indicated, and they are important in proportion as the symptoms denote failure of the vital powers.

Bronchitis with Fibrinous Exudation.

A variety of bronchitis is characterized by a fibrinous exudation on the inflamed mucous surface. This characteristic feature is expressed in various names: diphtheritic, pseudo-membranous, plastic, croupous, or croupal, have been applied to it. It is frequently associated with inflammation of the larynx and trachea, attended with a similar exudation, constituting the affection known commonly as true croup and occurring also in certain cases of diphtheria. But reference is here made to bronchitis with this peculiar exudation occurring independently of a similar affection of the larynx and trachea. Exclusive of the cases in which it accompanies croup and diphtheria, it is a rare variety of bronchitis. The exudation is similar to that in bronchitis secondary to croup. It forms a dense membraniform layer, which at first is closely agglutinated to the mucous surface, but sooner or later, loosened and detached by a suppurative process, is expectorated. When expectorated, the false membrane, as it is called, either has the form of patches or strips, or is thrown off entire from portions of the bronchial tubes, and when carefully displayed may be found to consist of casts representing more or less the form of the bronchial subdivisions. Aside from the form of casts of the tubes, the mucous character of the expectorated matter may be ascertained by microscopic examination and by chemical reagents. It presents the fibrillæ which characterize exuded fibrin in other situations. Placed in a solution of acetic acid it becomes swollen, whereas mucus contracts and is thereby rendered dense.

The fibrinous casts are expectorated in a globular mass enveloped in mucus, and without close examination they are liable to be overlooked. When the mucus is carefully removed, the casts, displayed in liquid, sometimes represent a bronchial stem of considerable size with subdividing branches which extend to the smallest ramifications. These exudative casts are to be distinguished from those produced by the coagulation of blood within the tubes in some cases of bronchorrhagia. The latter do not, like the former, present laminae or concentric layers, and they contain blood-corpuscles in greater quantity. They are of course preceded by hæmoptysis.

The inflammation in cases of bronchitis with fibrinous exudation is acute, subacute, or chronic. Occurring in young children, it may occasion sufficient obstruction to seriously compromise respiration, and it frequently proves fatal. Affecting adults, however, if not complicated with other affections, it rarely destroys life, and in the majority of cases the recovery is complete. I have met with a case in which it was associated with emphysema. Fibrinous bronchitis has been associated in many cases with phthisis. I have known it to occur in connection with acute pneumonia. [It has also been observed in association with skin diseases, such as eczema, pemphigus, and herpes, and the view has been entertained that in such cases the bronchial affection is a localization of one of the cutaneous affections.—H.]

There are no symptoms or signs by means of which the diagnosis of this variety of bronchitis can be made out prior to the expectoration of false membrane or bronchial casts. When this occurs the character of the affection is of course manifest. This expectoration is preceded and accompanied by violent paroxysms of coughing. It is followed by a muco-purulent expectoration, which may be bloody. The symptoms are relieved by the removal of the fibrinous exudations or casts. The expectoration of the latter may be repeated after intervals of days, weeks, months, or even years. The character of the disease, if it prove fatal before the expectoration of false membrane takes place, may be suspected, but the symptoms and signs show only the existence of bronchitis with obstruction of bronchial tubes and perhaps collapse of pulmonary lobules. This variety of bronchitis sometimes recurs repeatedly in the same person. I have met with cases in which a large number of bronchial casts (forty or fifty) were expectorated at as many different times.

The principles of treatment are essentially the same as in cases of acute or chronic bronchitis without this peculiar feature, and they need not be separately considered. Warm vapors or sprays inhaled will aid in the separation of the false membrane, [and they may be medicated with carbonate of sodium or potassium (1 per cent.), both of these substances being solvents of fibrin. Pilocarpine has been suggested as a remedy likely to prove effective in these cases, on account of its property of producing a copious liquid secretion from the bronchial mucous membrane. Mercury and potassium iodide have been administered with the object of preventing a return of the paroxysms, and with apparent success. If possible, the winters should be spent in a climate, such as the sea-coast of Florida, where the air is both warm and moist.—H.]

Circumscribed Bronchitis.

As already stated, bronchitis when circumscribed is incidental to some other pulmonary disease. It is developed in pneumonitis, being limited to the lobe or lobes affected, and is the chief source of the expectoration in this disease if it do not go on to the suppurative stage. It occurs in pulmonary phthisis, and is limited to the tubes in proximity to the seat of the deposit of tubercle. The bronchitis in this disease furnishes the expectoration prior to the softening and discharge of the tuberculous product. As thus developed, bronchitis claims no special attention in a therapeutical point of view.

Chronic Bronchitis—Fetid Bronchitis.

Chronic bronchitis may follow the acute form or it may be subacute from the beginning. It is far less frequent than acute bronchitis. It occurs much oftener in aged persons than during the early and the middle period of life. It is associated with asthma, pulmonary emphysema, and cardiac lesions, especially those involving mitral stenosis or incompetence of the mitral valve, [and is not infrequently a manifestation of some underlying constitutional condition such as gout, rheumatism, or renal disease.—H.]

The hyperæmia is less intense than in acute bronchitis. The color of the mucous membrane may be bluish-red or it may be grayish or slate-colored. The morbid products upon the membrane are similar to those in acute bronchitis, but usually with greater predominance of mucus. More extensive changes, however, may occur in the bronchial wall. This, on the one hand, may become thickened by the development of new connective tissue, or it may become thinned in consequence of atrophy of the connective tissue and

miscible in water, and in water it sinks to the bottom. These differential characters are combined in varying proportions when the matter of expectoration is muco-purulent.

The matter of expectoration in some cases of chronic, as also of acute bronchitis, is notably fetid, having the characteristic odor of decomposed animal substances. The affection is then said to be *fetid bronchitis*. Generally, this characteristic fetor denotes either gangrene of lung, bronchitis with dilated bronchial tubes, or decomposition of matter within phthisical cavities; but it may occur independently of any of these conditions. Gangrene may be excluded by the absence, on microscopical examination, of any appearance of expectorated pulmonary tissue, and dilated tubes by the absence of the signs of that physical condition. The diagnosis is to be made by excluding these diseases, together with pyothorax and perforation of lung, the expectoration in the latter sometimes having a notable degree of fetor. The explanation of fetid bronchitis is that circumstances pertaining to morbid products within the tubes are favorable for the action of the putrescence-producing bacteria derived from the atmosphere. [The quantity of expectoration in these cases is generally large, and on standing it separates into three layers, of which the uppermost is frothy and contains masses of muco-purulent material; the lowest presents a granular appearance, and is largely composed of small yellowish masses, the so-called Dittrich's plugs; the intermediate layer is of a serous appearance. It is the lowest layer, and especially the plugs of Dittrich, which are characteristic of fetid bronchitis and impart to the sputum its fetor. When examined microscopically the "plugs" are found to be mostly composed of minute organisms, among which the *leptothrix pulmonalis* is predominant. They may contain, besides, fat-granules, pus-corpuscles, and crystals of margaric.—H.]

Chronic bronchitis of course involves the same causes as the acute in the cases in which it is preceded by the latter. It may be produced and maintained by the inhalation of irritating particles of stone or metal in the exercise of certain occupations. Its continuance in some cases is referable to organic affections of the heart, consisting of obstructive or regurgitant mitral lesions. These act by inducing pulmonary congestion. It is an affection incident to old age, occurring without any obvious causative agencies. It occurs in youth and middle age irrespective of apparent causes, and is often associated with asthma and emphysema. To these affections it stands in the relation of a cause rather than an effect. In cold latitudes it is sometimes manifestly dependent on climatic causes, recurring with each successive winter, and disappearing during the summer season or on removal to a warm climate ("winter cough").

It is not an affection which tends directly to destroy life. In the aged it may sometimes predispose to the development of capillary bronchitis, and thus indirectly prove serious. In connection with the feebleness of advanced years it may lead to collapse of pulmonary lobules, and in this way shorten life. Its existence in a patient prostrated with any other disease involves danger from the accumulation of morbid products in the bronchial tubes. It may lead to the development of asthma and pulmonary emphysema—affections which, although not immediately dangerous, diminish the duration of life. Aside from these contingencies, the evil to be apprehended is the permanency of the affection. It is liable to become established, persisting for years, and in aged persons for the remainder of life. The existence of chronic bronchitis does not involve an increased liability to the development of pulmonary phthisis.

The DIAGNOSIS of chronic bronchitis involves discrimination from pulmonary phthisis. This would be difficult, and sometimes impossible, were the inves-

tigation to be limited to the symptoms; hence before physical signs were studied these two affections were of necessity confounded. The importance of the discrimination is obvious in view of the great difference between the affections as regards prognosis. The differential diagnosis is to be based on the absence of the symptoms and signs which are diagnostic of phthisis. In other words, it is concluded that the latter does not exist, from negative evidence or reasoning by way of exclusion. The absence of symptoms which belong to the clinical history of phthisis is also to be considered, such as progressive marked emaciation, hæmoptysis, and accelerated breathing. These symptoms are wanting in chronic bronchitis. The physical signs in this variety of bronchitis are the same as in the acute form—namely, the presence of dry and moist bronchial râles, the resonance on percussion and the vocal resonance unaffected, and the respiratory murmur weakened and sometimes suppressed over a portion of the chest from temporary obstruction of bronchial tubes, but its characters, aside from weakness, unchanged. The parasitic doctrine of phthisis has rendered the microscopical examination of the sputum important in the differentiation of this affection from chronic bronchitis. The absence of the bacillus tuberculosis in a single specimen, however, is not sufficient to exclude phthisis, but the negative result in repeated examinations goes far toward the exclusion of that disease.

The coexistence of pulmonary emphysema is to be determined by symptoms and signs diagnostic of this affection, which will be considered in the next chapter.

In the TREATMENT of chronic bronchitis bloodletting or other depletory measures are never indicated. The affection seldom exists under circumstances which render it desirable to lower the powers of life. Counter-irritation by means of croton oil or stimulating liniments is sometimes useful. The diet should be nutritious, but not stimulating, consisting of milk, eggs, fowl, fish, and farinaceous articles. Meat, however, is not to be interdicted if the system be enfeebled. Wine and alcoholics are to be avoided, except when measures to support or strengthen the system are indicated. Attention to the surface of the body is important. In a cold or variable climate woollen or silk garments should be worn next the skin. An undergarment of buckskin or chamois leather, worn over light woollen or silk, affords during cold weather great protection and saves the inconvenience of an undue quantity of clothing. The object is to secure uniformity of the temperature of the surface and to maintain the functions of the skin.

Medicines may be employed with a view to palliation and cure. If cough be troublesome, exceeding that required for expectoration, soothing remedies are called for. Opium, however, is to be prescribed with circumspection; in the first place, lest the habit of using it be formed—a consideration to be taken into account in all chronic affections; and in the second place, in feeble subjects and under circumstances in which there may be danger from an accumulation in the bronchial tubes, serious consequences may follow blunting that sense of the presence of morbid products which induces acts of expectoration. Moreover, the use of opium tends to impair the digestive powers. For these reasons other anodynes, such as hyoscyamus, conium, belladonna, and hydrocyanic acid, are generally to be preferred.

As a rule, the remedies which are called expectorants are not indicated. The nauseant expectorants do harm by their depressing effect and by disturbing the appetite and digestion. The stimulant expectorants, such as squills, senega, etc., are of doubtful efficacy, and if not useful are more or less hurtful.

Certain remedies, however, sometimes exert a curative effect. The iodide of potassium (or the iodide of ammonium) is one of these, and perhaps the one

most likely to be successful. Five or ten grains three or four times daily may be given at first, and before abandoning the remedy as useless the dose should be increased to the limit of tolerance. [The remarkable efficacy of this drug in many obstinate cases is probably due to the fact that the bronchitis is the sole manifestation of a gouty, rheumatic, or syphilitic constitution.—H.] This remedy is not always tolerated even in moderate or small doses, and it is by no means always successful, even when large doses occasion no inconvenience. The muriate of ammonia is in some cases a curative remedy. I have known it to effect a prompt cure, the disease having existed for ten years. The balsam of copaiba is a remedy the value of which in this disease is not generally appreciated. It has no value in certain cases, but its curative effect is sometimes so marked that it would seem to be almost a specific remedy. The spirits of turpentine occasionally prove equally efficacious. A good method of giving the latter is in what the late Prof. Clark of Boston called the continuous dose—namely, a drop in an emulsion every one or two hours throughout the day. Other balsamic remedies, the balsams of Tolu, Peru, and sandal-wood, are among the curative remedies, to which are to be added terebene, tar, and the compound tincture of benzoin. The bromine salts are to be mentioned as useful remedies. This list might be extended. As an illustration of the great number of remedies which have been found useful in bronchitis, the National Dispensatory enumerates under this head one hundred and twenty-two articles.

Frequently, marked benefit as regards the bronchitis is derived from tonic remedies in conjunction with measures to invigorate the system. The salts of quinia and the preparations of iron are often highly useful. These and other tonic remedies are indicated if the powers of the system be reduced or the patient be anæmic. A generous diet is to be conjoined, and wine or alcoholics may be taken moderately with advantage. Out-of-door life in such cases should be added. This plan of treatment is applicable to a pretty large proportion of the cases of chronic bronchitis; and to improve the general health and restore vigor are important objects in the treatment of this as of any other chronic local affection.

It is an object of treatment in some cases to diminish the amount of expectoration when this is excessive. For this end astringent remedies may be prescribed, such as tannic acid, the persulphate or pernitrate of iron, and the preparations of zinc. After a bronchitis, however, has become habitual, especially in the aged, it sometimes appears to be, as it were, an element of health. At all events, patients complain of the discomfort arising from the suspension or diminution of the expectoration, and for this reason opiates do not afford relief. Under these circumstances expectorants are useful as palliatives.

The inhalation of the spray from medicated liquids, produced by an atomizer, may be resorted to for several objects. A solution of the astringent remedies just named may sometimes be useful as a topical application in the form of a spray, with a view to diminish profuse expectoration. Oftener it is an object to facilitate expectoration. Spray from a solution of the muriate of ammonia—gr. j to gr. xv to the ounce—is useful in this way. Opium and other narcotics brought into direct contact with the affected membrane may be of service by allaying the irritation which occasions troublesome superfluous cough. The vapor of tar is a soothing application. In fetid bronchitis antiseptic inhalations are indicated. For this object the vapor of the oil of turpentine—a solution of carbolic acid from gr. j to grs. iv to the ounce, in the form of spray—may be inhaled, or a similar strength of a solution of permanganate of potassa. The bisulphite of soda in scruple doses, given every two hours by the mouth, is an efficient antiseptic. Medicated spray is to be

employed with care as regards the strength of the solutions atomized and the frequency or continuance of the inhalations, bearing in mind that remedies held in solution pass rapidly into the blood and may produce toxic effects.

[Pneumato-therapy has been used advantageously in the treatment of chronic bronchitis, and is most effective in cases which are complicated with asthma and emphysema.—H.]

Change of climate is sometimes advisable. A removal from a cold and variable climate to a situation in which the temperature is mild and equable may be attended with marked relief, and perhaps lead to recovery. Benefit may be looked for especially in the cases in which there is either immunity from the disease or marked amelioration during the summer season.

CHAPTER X.

EMPHYSEMA OF THE LUNGS.—ASTHMA.—PERTUSSIS.

Emphysema of the Lungs: Varieties; Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Asthma: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Pertussis, or Whooping Cough.

Emphysema.

EMPHYSEMA in general signifies the presence of air in the interstitial connective tissue. In the lungs, however, it is necessary to distinguish two kinds of emphysema. In one form there is an escape of air into the interlobular and subpleural connective tissue. This form is analogous to emphysema in other situations, and is called *interlobular* or *interstitial emphysema*. The other and the more common variety is called *vesicular emphysema*, and consists in an abnormal accumulation of air within the air-cells, whereby they become distended and their walls often atrophied.

Interlobular emphysema arises from rupture of the air-cells, causing a communication between them and the interlobular connective tissue. This sometimes follows perforating wounds of the chest or injury of the lung by the extremity of a fractured rib. It may also result from violent paroxysms of coughing, as in whooping cough, especially when the lung has been previously affected with vesicular emphysema. Its favorite situation is the anterior border of the upper lobe. Just beneath the pleura little air-bubbles, often arranged like rows of beads, can be seen in the course of the septa between the lobules. The air sometimes detaches the pleura so as to form air-blebs of considerable size. A subpleural air-tumor may be as large as an English walnut or even larger. Bouillaud has reported a case in which an air-tumor existed as large as the stomach. It is important not to mistake for interlobular emphysema a post-mortem generation of gas in the interstitial tissue of the lungs as a result of decomposition—a condition not infrequently found after death. In rare cases the subpleural air-blebs rupture during life, and pneumothorax, with or without pleuritis, results. Another very rare occurrence is the passage of the air from beneath the pleura along the root of the lung into the connective tissue of the mediastinum, and thence into the subcutaneous tissue of the neck. In this way the emphysema may become diffused over more or less of the body.

Vesicular emphysema—and this is usually meant when the term pulmonary emphysema is used—may occur as an independent affection preceded or accompanied by chronic bronchitis. This is known as *substantive* or *idiopathic emphy-*

sema, in distinction from *vicarious*, *compensatory*, or *symptomatic emphysema*, the latter terms being applied to an abnormal accumulation of air in the air-cells of certain portions of the lung when the penetration of air into other portions has been obstructed; as, for instance, by pneumonitis, tuberculous deposits, tumors, effusions in the pleural cavity, pleuritic adhesions, occlusion of the bronchi, etc. Vicarious emphysema does not necessarily appear in the immediate neighborhood of the obstructed alveoli. Like all forms of emphysema, it affects most frequently the anterior borders and the upper lobes of the lungs. When one lung is compressed or hepatized the other is often emphysematous.

The names *acute emphysema* and *insufflation* are given to a dilatation of the air-cells frequently met with in the lungs of those who have suffered from severe dyspnoea during the last days or hours of life. It is usually observed in the apices and the borders of the lungs. The air-cells may be dilated to twice their normal volume. The elasticity of the alveolar walls is impaired, but in distinction from chronic emphysema they present no evident structural changes. Acute emphysema or insufflation of the lungs accompanies chiefly acute diseases of the respiratory organs or other diseases terminating rapidly with dyspnoeic symptoms. It is due to repeated forced inspiratory efforts.

In a well-marked case of chronic vesicular emphysema the lungs are enlarged. Upon opening the chest they do not retract like healthy lungs, but remain in contact along their anterior borders, so that the pericardium may be covered. Their contractility is impaired. The diaphragm may be pushed down to the seventh or eighth rib, and the adjacent viscera correspondingly displaced. The heart is pushed downward and backward, and in consequence of hypertrophy and dilatation of the right ventricle, which are usually present, extends farther to the right than normal. The borders of the lungs are rounded and puffy; the emphysematous portions do not crepitate upon pressure or incision, as do normal lungs, but have a soft, cushiony feel. The imprints of the fingers remain a long time. The lungs appear in general pale, anæmic, and dry, but often present patches and striæ of black pigment. The dilated air-cells can be distinguished with the naked eye. The air-spaces, much larger than a pin's head, are the result of rupture of the interalveolar septa and coalescence of the air-cells. Such air-spaces or blebs frequently attain the size of a pea, and they may be considerably larger. Large air-blebs, from the size of a pea to that of a pigeon's egg, sometimes project above the lung-surface, and may become so detached as to be pedunculated. Upon microscopical examination it is seen that the dilatation begins in the alveolar passages and infundibula. They become expanded and the alveolar septa are less prominent. The alveolar walls are thinned, and finally become perforated, at first usually in their centres. The holes between the alveoli enlarge, and the air-cells coalesce, so that by continuation of the process larger and smaller air-sacs are formed. The process appears to be a gradual atrophy of all of the elements composing the alveolar walls. The finer elastic fibres early disappear, the larger ones diminish in size and frequently rupture, and the capillary network becomes coarser by obliteration of a certain number of capillary vessels. This destruction of pulmonary capillaries is not attended with hemorrhage, as the vessels become impermeable before they disappear. The most important symptoms of emphysema are referable to this loss of pulmonary blood-vessels. A partial compensation for this disturbance of the pulmonary circulation exists in the anastomoses between the pulmonary and the bronchial and subpleural vessels. Fatty particles are often found in the alveolar walls, probably from fatty degeneration of the alveolar epithelium and of the capillary endothe-

lium. An apparent thickening of the alveolar walls may result from their being compressed and crowded together by dilated air-vesicles. Rindfleisch, however, claims to have seen an actual hypertrophy of the smooth muscular elements which, according to him, exist in the alveolar walls. There is nothing in the pathological appearances of chronic emphysema which supports the view, otherwise not improbable, that a primary vice of nutrition in the alveolar walls antedates the development of the emphysematous condition in many cases. Substantive emphysema is most developed in the upper lobes and along the anterior borders of the lung, also along the lateral borders of the base of the lung; but it may be diffused over the whole lung-surface and in its substance. It is accompanied by chronic bronchitis, which may either precede or follow the emphysematous condition. The bronchial mucous membrane is coated with mucus, the bronchial wall may be thickened, and sometimes dilatations of the bronchi are present. In consequence of the obliteration of pulmonary capillaries there is obstruction to the flow of blood through the lungs, leading to hypertrophy and dilatation of the right ventricle, and frequently to venous congestion in the various viscera. The enlargement of the heart is compensatory so long as hypertrophy predominates over dilatation; but it becomes a source of grave consequences when the latter predominates, giving rise to chronic congestions of the liver, spleen, kidneys, stomach, and intestines. These conditions are similar to those met with in valvular lesions of the heart, and will be more fully described in another connection.

The emphysematous condition, especially in vicarious emphysema, may be limited to a few vesicles. Its practical importance of course depends upon the extent of lung involved.

A pathological condition of the lungs which bears little resemblance to true emphysema has received the name of *senile emphysema*. It is also called senile atrophy of the lungs. Here, instead of an abnormal accumulation of air in the lungs, these organs are smaller and contain less air than normal. In consequence of atrophy of the alveolar walls the air-cells coalesce and form larger air-spaces. These, however, do not result from a dilatation of the alveoli, but from a gradual shrinkage and disappearance of the lung-tissue. These atrophic lungs are usually deeply pigmented, and take up less space than normal in the thoracic cavity. Senile atrophy of the lungs does not lead to hypertrophy of the right ventricle.

Emphysema developed in a person free from tubercle undoubtedly diminishes the liability to tuberculous disease. The two affections are rarely associated, exclusive of the cases in which pulmonary lobules in the vicinity of tuberculous deposits become secondarily emphysematous. In these cases the emphysema is vicarious. A reason for the protection against tubercle afforded by emphysema may perhaps be found in the diminished quantity of blood within the emphysematous portions of lung, and in the fact that the portions affected with emphysema—namely, the upper lobes—are the primary seat of tubercle in the immense majority of cases. The condition of emphysema is also, to some extent, incompatible with hæmoptysis. Pneumonitis, as a rule, is not developed in an emphysematous patient. I have met, however, several exceptions to this rule.

CLINICAL HISTORY.—Emphysema, existing to an extent to compromise considerably the respiratory function, is characterized by habitually labored breathing and inability to take active exercise without suffering from want of breath. The labored breathing is manifested especially in expiration. The rhythm of the respiratory acts is altered; the inspiration is shortened and the

expiration prolonged. As chronic bronchitis generally coexists, cough and expectoration are habitually more or less prominent as symptoms. The cough is usually violent, paroxysmal, and characterized by a series of prolonged, spasmodic expiratory efforts, as in whooping cough. The expectoration varies much in different cases as regards quantity and character. The acts of expectoration are difficult, and the sputa are frequently accompanied by an abundant, frothy, serous liquid resembling soapsuds. Not infrequently sputa streaked with blood are expectorated.

The affection is chronic and unaccompanied by fever. The pulse is feeble and the body cool. Owing to an accumulation of blood within the right cavities of the heart, the surface of the body presents venous congestion, and this, together with deficient oxygenation of the blood, may give rise to a cyanotic hue. In extreme cases lividity is marked. The paroxysms of coughing are accompanied with great congestion of the face and turgescence of the cervical veins. Symptomatic phenomena, aside from those referable to respiration and circulation, are accidental. The appetite and digestion may not be notably impaired; the body for a considerable period may be well nourished, but after a time slow, progressive emaciation takes place. The countenance has an expression of distress which, conjoined with tumidity and a dingy or livid hue, renders the physiognomy somewhat characteristic. At an advanced period anasarca may occur as a consequence of dilatation of the right side of the heart. Albumen in small quantity may be found in the urine, this being an effect of congestion of the kidney; and congestion of the liver and spleen may render these organs appreciably larger than in health.

These symptoms accompany the affection when it exists to an extent to considerably compromise respiration. Existing in a moderate or slight degree, there is no habitual want of breath or labor of breathing. But the respiration is disturbed by active exercise; the patient is short-winded on attempting to run or walk fast; and this difficulty is apparent also in speaking, singing, and especially in paroxysms of laughter. Cough and expectoration are usually present, having the same characters as when the affection exists to a greater extent, but less marked. Congestion, tumidity, and lividity are present—not habitually, but during paroxysms of coughing or any violent physical exertion. The functions of the body generally may present little or no disturbance. Different cases exemplify all gradations between the two extremes as regards the symptoms belonging to the affection.

Many persons affected with emphysema are subject to paroxysms of labored respiration and dyspnoea which are due to another affection—namely, asthma. Acute ordinary bronchitis occurring in a person affected with emphysema occasions symptoms of embarrassed respiration, which do not belong to the clinical history of bronchitis occurring in a healthy person. The reason of this is to be found in the anatomical changes which characterize emphysema.

The development of emphysema is generally slow. In the majority of cases the previous history shows the origin of the affection, as indicated by deficiency of breath on exercise, to be dated back many years, frequently extending to childhood, and not infrequently beyond the recollection of the patient. Exceptionally, it may be developed with rapidity. Notable temporary emphysema occurs in paroxysms of asthma and in cases of capillary bronchitis. The affection has no fixed duration, usually continuing and progressively increasing during the patient's lifetime.

PATHOLOGICAL CHARACTER.—Exclusive of the senile or atrophic variety, emphysema involves permanent dilatation of the air-cells, with, frequently, more or less destruction of the cell-walls and coalescence of the cells. In

so far as destruction of air-cells takes place, it is obvious that the area of the respiratory surface is diminished, and the function of respiration in this way compromised. The dilatation of the cells involves a loss of the elasticity of the lungs, so that the accumulation of air within the cells offers an obstacle to the contraction of the chest in the act of expiration. Consequently, the air in the cells is not sufficiently renewed for the purpose of respiration, and the air stagnates in the cells. In these ways the affection compromises the respiratory function. The distension of the cells involves pressure upon the terminal branches of the pulmonary artery, and in this way the pulmonary circulation is obstructed. This obstruction is further increased by diminished respiratory function. The obstruction to the pulmonary circulation occasions an over-accumulation of blood in the right cavities of the heart; hence the venous congestion of the face and neck, and, to a greater or less extent, of the surface generally, with, in some cases, cyanosis. Hence, too, sooner or later supervenes dilatation of the right side of the heart.

The pathological character of emphysema furnishes an explanation of the symptoms which make up the clinical history of the affection. When the respiratory function is so far compromised that the functional capacity of the lungs is insufficient, while the respiratory acts are performed without effort, want of breath is felt and the respiration becomes labored. But if the emphysematous condition be slight or moderate, no difficulty is experienced habitually, because there is still functional capacity enough for ordinary respiration. The quantity of lung in health exceeds the amount required, there being a reserve provided for any unusual demand on the respiratory function, as in muscular exercise. If, therefore, the extent to which the respiratory function be compromised do not exceed the amount of lung held in reserve, no difficulty is experienced save when an extra demand is made on the function. Under these circumstances exercise, which involves an extra demand, cannot be taken without the want of breath being felt. The patient, who is habitually using the lungs to their fullest functional capacity, is disturbed by any interference with respiration. Ordinary bronchitis, which in a healthy person requires only a little of the reserve lung to be brought into play (a fact of which the patient is not conscious), occasions, if there be no lung in reserve, difficulty arising from the slight diminution of the calibre of the larger bronchial tubes which is incident to this disease; hence, patients with emphysema existing to much extent suffer from dyspnoea and labored breathing in ordinary bronchitis. The cough in connection with emphysema arises from the coexisting bronchitis, and the difficulty of expectoration is in consequence of the impaired elasticity of the lungs, the expiratory efforts in coughing not being brought to bear readily on the contents of the bronchial tubes.

The venous congestion of the face and of the surface generally is due to obstruction caused by over-accumulation of blood in the right cavities of the heart. The lividity is in a great measure due to the same condition, but in part perhaps to deficient oxygenation of the blood. The smallness and weakness of the pulse also proceed from an obstruction to the free passage of the blood through the pulmonary circuit.

CAUSATION.—The mode in which dilatation of the air-cells is produced has given rise to much discussion. Laennec, who was the first to describe distinctly this lesion, attributed it to obstruction of the bronchial tubes from the products of bronchitis. Regarding the inspiratory act as more powerful than the expiratory, he supposed air to be forced through imperfectly obstructed tubes in inspiration, and to remain imprisoned in the cells in consequence of the want of sufficient expulsive force in expiration. The dilatation, according to this theory, is produced by the rarefaction of the imprisoned air by

heat, and by the reaction of the force of expiration in coughing, etc. upon the cells already filled with air. This theory is certainly not tenable in view of the fact that of the two acts of respiration the expiratory is a third more forcible, and still more when voluntary and spasmodic efforts are brought to bear upon it. The more powerful the efforts of expiration in coughing, etc., the less ought to be the liability of accumulation of air in the cells communicating with obstructed tubes. An explanation of the mode of production has been advocated by Gairdner of Glasgow which differs essentially from the theory of Laennec. Gairdner attributes the affection to obstruction of bronchial tubes incident to bronchitis; but he supposes that the obstruction from collections of plugs of mucus leads to collapse, instead of dilatation, of the cells which communicate with the obstructed tubes, in the manner already adverted to in the chapter on Broncho-pneumonitis (p. 88). The current of air in the act of expiration may remove the mucus from its situation in tubes of small size into larger tubes, where the obstruction is less; but the effect of the inspired current will be to carry it back from the larger to the smaller tubes, the mucous plugs thus acting like a ball-valve upon the orifice of a syringe, obstructing the entrance of air to the cells, but permitting the escape of air from the cells. Moreover, owing to the greater force of the expiration, the expired air may be driven past obstructions which arrest the current of air in inspiration. Collapse of more or less of the pulmonary lobules being thus produced, a larger amount of air enters the cells communicating with unobstructed tubes, and these cells become consequently dilated. The dilatation of cells, in other words, is supplementary to the diminished volume of the lungs due to collapsed lobules, and is produced under these circumstances in the act of inspiration. In support of this explanation, Gairdner states that observation shows the tubes connected with emphysematous lobules to be unobstructed, and that close examination of lungs affected with emphysema will show the traces of collapsed lobules. Moreover, experiments of introducing into the air-tubes in inferior animals foreign bodies, such as shot and wads of paper, have been found to lead to collapse of lobules connected with the tubes in which these bodies become lodged, and dilatation of lobules connected with other tubes. This explanation will account for the production of emphysematous lobules so frequently found in connection with tuberculous deposits, the latter inducing solidification and diminished volume of the portion of the lungs in which they are situated. The term *vicarious emphysema* expresses the fact that it is supplementary to diminished volume of lung.

There is reason to believe that by prolonged, forcible efforts of expiration, as in long-continued exertions at lifting or pulling, playing on wind instruments, glass-blowing, or in voluntarily blowing through a partially obstructed tube in the manner which has been to some extent practised as a means of preventing and curing consumption, the elasticity of the lungs may be diminished and permanent dilatation produced. It is well known that the chest may be in this way considerably enlarged, and deficiency of breath on exercise is sometimes a result. Expiratory efforts thus may sometimes co-operate with collapse of pulmonary lobules in the causation of emphysema. The paroxysms of whooping cough and the labored efforts of breathing in attacks of asthma may be more or less involved in the causation.

The mechanism of the causation of emphysema by expiration is as follows: During violent acts of coughing the glottis is contracted and offers an obstacle to the free escape of air, and the muscles involved in the acts of coughing exert their effect especially upon the inferior portion of the chest. Under these circumstances the air, not escaping through the glottis, distends the upper lobes of the lungs, and this distension, often repeated, leads to dilata-

tion of the air-cells in these lobes. This explanation accounts for the fact of the upper lobes being especially the seat of emphysema, and that the anterior portions of the chest in some cases project beyond the limits of a forced inspiration in health. It is obvious that this explanation applies also to the production of emphysema by forcible acts of expiration produced otherwise than in coughing. Accepting this explanation, the fact that physical signs show emphysema, as a rule, to be more marked in the left than in the right upper lobe may be thus accounted for. In coughing and all forcible expiratory efforts the lower portion of the chest is more contracted on the left than on the right side, owing to the presence of the liver on the latter side.

The force with which the distension of the upper lobe takes place in violent coughing is appreciable by palpation over the clavicles and between the ribs in thin persons. It was strikingly exemplified in the case of Groux, in whom there was a congenital absence of a portion of the sternum. Forcible bulging within this wall was produced by coughing and by voluntary strong expiratory efforts.

The inspiration theory, as set forth by Gairdner, suffices to explain vicarious emphysema, but the expiration theory seems necessary for the explanation of substantive or idiopathic emphysema. Something, however, in addition to violent expiratory efforts is requisite, in view of the fact that a comparatively trifling expiratory pressure will produce the affection in one person, while in many persons severe paroxysms of coughing, etc., continued for a long time, do not occasion it. This view is supported by another fact—namely, that heredity is involved in the causation. Giving proper weight to these facts, it may be assumed that in many if not most cases a causative condition is some error of nutrition which impairs the elasticity of the alveolar walls.

The diminution of the elasticity of the ribs and costal cartilages incident to advancing age favors the production of emphysema. This change involves diminished extent and force of expiration, with undiminished, if not increased, power of inspiration. The result is, when the chest is expanded in inspiration, the lungs already contain a surplus of air. The lessened elasticity of the lungs in old persons has the same effect, keeping the organs permanently expanded.

The fact that emphysema belongs among the hereditary affections was first established by James Jackson, Jr., of Boston, who found that in 18 out of 28 cases one or both parents had been similarly affected. The affection may be developed at any period of life. In a large proportion of cases it begins in infancy or childhood. Its slowly progressive increase explains the fact that patients frequently attain middle life before the affection has advanced sufficiently to occasion great inconvenience.

DIAGNOSIS.—The symptoms described under the head of the Clinical History render the affection probable when it compromises considerably the respiratory function. The probability is increased by the coexistence of asthma in a large proportion of cases. The physical signs, however, render the diagnosis positive, and when the affection is moderate or slight the signs are indispensable to the diagnosis. If asthma be not associated, patients are often supposed to have phthisis by those who rely on the symptoms in making the diagnosis.

The enlarged volume of the upper lobes of the lungs in certain cases of emphysema gives rise to distinctive signs obtained by inspection. In the cases in which the characters of the "emphysematous chest" are strongly marked the diagnosis may be at once made with the eye. The upper and middle thirds of the chest on its anterior aspect are expanded, and present a globular or barrel-shaped form. This projection extends from the summit to

the sixth rib. The obliquity of the ribs is diminished, and the angle formed by the junction of the ribs with the costal cartilages is more obtuse than in health. The inferior portion of the chest is relatively and actually contracted. The dorsal spine becomes curved anteriorly. In extreme cases these changes amount to a deformity which is highly characteristic. The superior costal respiratory movements are lessened, and in labored breathing the ribs and sternum are raised together, as if they formed a solid bony case. The lower anterior portion of the chest is contracted, and the soft parts above the clavicles and sternal notch are depressed in inspiration. The chest is drawn permanently upward by the sterno-cleido-mastoid muscles and the scaleni, so that the neck appears to be shortened. The upper part of the chest during the act of expiration is in the same condition as at the end of a forced inspiration. The intercostal depressions are usually strongly marked. The heart's impulse is frequently seen and felt in the epigastrium.

These visible changes are present in cases in which the emphysema exists to an extent to compromise considerably the function of respiration, and in which the volume of the lungs is notably increased. The signs are more marked on the side in which the emphysema is greatest, this side being, in my experience, generally the left. If the emphysema be comparatively slight or moderate, the size, form, and movements of the chest will not be sensibly altered. An abnormal relative fulness, however, may be observed on one side below, and perhaps above, the clavicle, with deficient superior costal movement. This disparity of the summit between the two sides as regards size and mobility is to be distinguished from a similar disparity due to contraction of one side from phthisis.

Percussion elicits an abnormally intense resonance, the character of the resonance being altered. The vesicular and the tympanitic quality are combined; that is, the resonance is vesiculo-tympanitic. This vesiculo-tympanitic resonance is more marked on the side corresponding to the lung which is the more emphysematous; that is, generally the left side. The exaggerated resonance being greater on one side, care must be taken not to consider the resonance as diminished on the side in which it is less exaggerated. The pitch of the resonance is always higher on the side which yields the greater resonance, whereas if the disparity be due to diminished resonance or dullness on one side, the pitch is higher on that side. That the resonance is vesiculo-tympanitic over the upper lobe on the side on which it is least marked—that is, usually the right side—may be shown by comparing this resonance with that over the lower lobe on the same side.

The murmur of respiration is weakened in proportion to the degree of the emphysema. If the affection exist to such an extent that the respiration is habitually labored, the inspiratory sound may be shortened (deferred) and the expiratory sound prolonged. The expiratory sound, however prolonged, is lower in pitch than the inspiratory, as it is in health. The changes in intensity and rhythm are the only modifications proper to emphysema. Not infrequently over portions of the chest corresponding to parts of the lungs which are not highly emphysematous the labored efforts of breathing evolve an exaggerated vesicular murmur. The weakness and alteration of rhythm are likely to be more marked on the side corresponding to the greater degree of the emphysema. Sibilant and sonorous râles, due to coexisting bronchitis or asthma, are often present in cases of emphysema.

The normal relation between the two sides, as regards vocal resonance and fremitus, continues. In some cases, owing to the displacement of the heart, the resonance on percussion within the præcordial region is abnormally clear.

In arriving at the diagnosis by means of the foregoing signs, it is to be considered that other affections, such as phthisis, pleuritis, and pneumo-hydro-

thorax, are excluded by the absence of signs which should be found if these affections existed. The signs are also to be taken in connection with diagnostic points embraced in the clinical history—namely, the character of the cough and expectoration, the absence of marked emaciation notwithstanding the duration of the pulmonary symptoms, and in many cases the coexistence of asthma.

In the foregoing account reference has been had to the ordinary form of emphysema—namely, the form characterized by dilatation of the air-cells. The atrophic form, or senile emphysema, offers certain marked points of difference, especially as regards the physical signs on inspection. The size of the chest, instead of being increased, may be notably diminished. The obliquity of the lower ribs may be much greater than in health, leaving sometimes but little space between the base of the chest and the pelvis. The resonance on percussion may be diminished.

PROGNOSIS.—Emphysema, even in the cases in which it is most marked, rarely if ever involves in itself immediate danger. It is not a fatal affection *per se*, but it diminishes the power of the system to resist intercurrent or superadded diseases. It leads to dilatation of the heart, which further impairs the ability to overcome other diseases. But, aside from danger to life, it is an affection which, if it exist to an extent to compromise respiration, incapacitates for physical exertion and renders life uncomfortable. Existing in a less degree, it is a source of much inconvenience and annoyance from the deficiency of breath on exercise.

In so far as it involves destruction of the alveolar walls and the coalescence of air-cells, it is an irremediable lesion. And in the majority of cases the dilatation of the air-cells which takes place is permanent; the tendency, in fact, is oftener to increase rather than to decrease. I have known, however, marked improvement to take place, as shown by the physical signs. In a case in which the enlarged volume of the upper lobes was sufficient to give rise to the characteristic deformity in a marked degree, the improvement was so great that the chest resumed nearly its normal form. In so far, therefore, as the lesion consists in dilatation of the cells, it is not necessarily irremediable.

TREATMENT.—The treatment of emphysema has reference, first and chiefly, to the bronchitis with which it is generally associated. The object is to relieve, and if possible remove, the bronchial inflammation. In proportion as the bronchitis is relieved the condition of the patient is rendered more comfortable, notwithstanding the emphysema continues undiminished; the emphysema is less likely to increase, and it may undergo diminution.

With reference to this object the measures to be pursued are those indicated in chronic bronchitis not connected with emphysema. The treatment, in fact, so far as this object is concerned, resolves itself into the treatment of chronic bronchitis, which has been considered in the preceding chapter. Trial should always be made of the iodide of potassium or of ammonium or of sodium. The effect is in some cases truly marvellous, but in other cases these remedies produce little or no effect. It may not be amiss to remind the inexperienced practitioner that some persons cannot continue the use of the iodide of potassium in consequence of great irritation of the fauces; and I have met with an instance in which it always produced violent vomiting and general disturbance. The eruptions on the face to which it frequently gives rise are an annoyance which may be submitted to if it exert a curative effect as regards bronchitis. When the remedy is well borne it may be continued, in moderate doses, for a long period without any unpleasant consequences. If moderate doses do not prove efficacious, they may be increased up to the limit of com-

fortable tolerance. The syrup of hydriodic acid is sometimes better tolerated than the iodides. The chlorate of potassa, the bromide of potassium, and the muriate of ammonia should also be tried if the iodide of potassium prove ineffectual. If these be unsuccessful, the various other remedies which experience has shown to be useful in cases of chronic bronchitis should be tried.

Tonic remedies and the regulation of diet and regimen with a view to invigorate the system form an important part of the treatment. If these measures fail, change of climate, if practicable, should be advised.

As there is reason to believe that violent paroxysms of cough contribute to perpetuate and increase the dilatation of the cells, palliative remedies for this symptom are called for, provided the bronchitis on which it depends cannot be removed. The effects of labored breathing in paroxysms of asthma probably have the same effect; and if this affection coexist, it is desirable, with reference to the emphysema, to relieve the paroxysms as speedily as practicable. It is important for the patient to avoid, as far as possible, attacks of acute bronchitis, and when they occur they should be cured as quickly as possible. Flatulence of the stomach or bowels and constipation contribute to dyspnoea by mechanically interfering with the play of the diaphragm. They are to be avoided by a regulated diet and appropriate remedies.

Exercise, as far as it can be taken without inconvenience, is not to be interdicted, but exertions which induce labored breathing are to be abstained from. Prolonged efforts of expiration, as in public speaking, singing, and straining at stool, are to be avoided.

The treatment by inhaling compressed air and breathing into rarefied air is recommended by German authors as often beneficial and sometimes effecting a cure. It has thus far found little favor in this country. Its employment requires caution lest it do harm. There is abundant testimony by competent observers of its value in cases of emphysema.¹

The affection distinguished as atrophic or senile emphysema admits of no permanent relief. Ethereal preparations and remedies to palliate dyspnoea, together with measures to support the system, comprise the treatment.

Asthma.

The term asthma, used in a properly restricted sense, is applied to a disease which has well-defined symptomatic features, and which, in the opinion of most authors at the present time, has an essential pathological condition—obstruction of the smaller bronchi, caused by spasm of their muscular fibres. The term has heretofore been applied in a loose way to dyspnoea dependent on different pathological conditions. For example, it has been customary to call the dyspnoea dependent on diseases of the heart, cardiac asthma. The true pathology of asthma—that is, of the individual or substantive disease to which the term should be restricted—seems to me clearly that just stated, namely, bronchial spasm. All, however, do not so consider it, and other opinions will be noticed in connection with the pathological character of the disease. Asthma has no anatomical characters. It is true that in the great majority of cases pulmonary lesions are found after death, particularly those which belong to chronic bronchitis and emphysema; but this fact shows only the frequent coexistence of these affections with asthma.

CLINICAL HISTORY.—Asthma is essentially a paroxysmal disease. The

¹ Vide article by Hertz in *Ziemssen's Cyclopædia*, Am. ed., vol. v.

clinical history will therefore consist of an account of the characters which distinguish asthmatic paroxysms, together with the laws of their recurrence and the condition of health in the intervals.

A paroxysm of asthma may begin without warning or it may be preceded by certain premonitions. The premonitions vary in different cases. Patients are often able to predict an attack for some hours before its occurrence, sometimes by a sense of drowsiness or heaviness; sometimes, on the other hand, by an unusual excitation of the mind; and, again, by sensations the significance of which they have learned by experience, but which are not easily described. The paroxysm may be slowly developed—that is, an hour or two, and sometimes a longer period, may be required for its full development—or the attack may be sudden and its greatest intensity quickly reached. It takes place in the great majority of cases, during the sleeping hours, and generally in the latter part of the night or very early in the morning.

The paroxysm is characterized by laborious efforts of breathing, prompted by a painful sense of the want of air, or dyspnoea. The patient is unable to lie down, but sits with the elbows on the knees or resting on some solid support, the mouth open and gasping with each inspiration. The respirations are not increased, but may be less in number than in health. The inspiratory act is performed with a spasmodic effort, and the expiratory act is prolonged and accompanied with a wheezing sound. Speech is difficult from the want of breath, and words are uttered with interrupted efforts. Movements of the body are dreaded, and changes of position are made slowly. Cold air, from its density, affords relief, and the patient desires the windows to be opened without regard to chilliness of the body. The face is pallid, and sometimes presents with the pallor a cyanotic hue, giving to the face a death-like appearance. Frequently perspiration is profuse. Limpid urine in great abundance is passed frequently, especially at the beginning of the paroxysm. The pulse is small and feeble, on account of an accumulation of blood in the right cavities of the heart due to obstruction to the pulmonary circulation. The surface of the body is cool or cold. The temperature, as shown by the thermometer, is either normal or subnormal. The nostrils are widely dilated. The countenance denotes extreme anxiety and distress. A frequent symptom is an itching sensation under the chin, which the patient endeavors ineffectually to relieve by rubbing, and the same sensation is frequently felt on the sternum and between the shoulders.

Paroxysms differ in severity. A patient suffering from a severe paroxysm presents a spectacle more distressing than can be well imagined, and to one not familiar with the disease he appears to be on the point of death. The suffering is considerable, even when the paroxysms are so mild as not to present to the spectator a picture of great distress. Their duration differs. They may continue for a few minutes only or for several days. Usually, after continuing for a few hours, either partial or complete relief occurs. If the relief be complete or nearly so, tranquil sleep follows, which is peculiarly sweet and refreshing. With the diminution of suffering there are usually cough and more or less expectoration.

Cough and expectoration may be absent during an asthmatic paroxysm. Usually, however, there is an expectoration of a small amount of viscid, transparent, frothy mucus. In this mucus are frequently found grayish particles which, upon close inspection, are found to contain peculiar mucous bands of varying length and diameter twisted in a spiral manner. These spiral bands often contain a central glistening thread. They are sometimes called "Curse-mann's spirals," from the author who has described them most fully.¹ The spiral cylinders or bands are doubtless moulds of the small bronchial tube.

¹ *Deutsches Archiv f. klin. Med.*, Bd. 32, p. 1.

and are probably composed of dense mucus. They are considered by Curschmann as evidence of a peculiar form of bronchitis which he calls *bronchiolitis crassativalis*, and which he believes to stand in intimate causative relation to asthma. The sputum also often contains pointed octahedral crystals of some organic substance. These are Leyden's crystals, and are believed by him to be, by their irritation, the cause in many cases of the asthmatic paroxysms. Both Curschmann's spirals and Leyden's crystals have been found in the sputum of persons not affected with asthma, and asthma may occur without the presence of either of these structures in the sputum. The expectoration is sometimes streaked with blood, and occasionally hæmoptysis takes place.

The paroxysms recur after intervals varying greatly in duration in different cases. They recur in some cases with great regularity after a stated period, and in other cases the recurrences are extremely irregular. Some patients suffer from a diurnal recurrence, and it is remarked by Salter that in these cases the affection is almost always associated with bronchitis or disease of the heart. Recurrence regularly after the interval of a week or a fortnight is not uncommon. Women sometimes have attacks only at the menstrual periods. Some persons experience an attack annually, and it may occur either in the winter or summer season. Examples of the latter are cases of so-called hay asthma, which will be noticed presently under another head. When the paroxysms recur irregularly they are sometimes attributable to a special exciting cause, but in other cases the reason of their recurrence is not apparent.

In the intervals the condition varies, the variations depending on the existence or otherwise of associated affections. Asthma is not infrequently associated with persisting chronic bronchitis, and under these circumstances more or less cough and expectoration are habitual. Emphysema is also a frequent concomitant, and deficiency of breath on exercise, or constant dyspnoea in proportion to the amount of emphysema, characterizes these cases. The habitual dyspnoea in these cases is due to the emphysema, and is not properly asthmatic. Dilatation of the heart is another affection not infrequently coexisting which may give rise to more or less dyspnoea.

PATHOLOGICAL CHARACTER.—The pathological character of asthma has been already stated in defining the term as applied to an individual disease. It is a neuropathic affection, tonic spasm of the bronchial muscular fibres being induced by a morbid excitation through the nervous system. The exciting causes of the paroxysms doubtless exert their effect through the excito-motor or reflex nerves. It is true that bronchitis generally exists at the time of the occurrence of the paroxysms, but bronchitis exists often enough without asthma, and cases occur in which the spasm takes place independently of bronchitis. In the latter cases the affection has been distinguished as nervous asthma; but, with the pathological view just presented, asthma is always nervous, and these cases differ from the majority only in the absence of coexisting bronchial inflammation. It is probable that inflammation renders the muscular fibres more prone to spasmodic action, and in this way it is involved in the production of the affection, not constituting, however, an essential part of it.

This view of the pathological character of the disease is believed to be substantially correct, but it is proper to state that opposing theories have been advanced by distinguished authors. Wintrich, Bamberger, and others contend that bronchial spasm does not exist in asthmatic paroxysms, but that the disturbance of respiration is to be attributed mainly to tonic spasm of

the diaphragm. This theory is based on the evidence of the diaphragm remaining depressed and immovable during an asthmatic attack, and on the fact that there is an abnormal expansion of the lungs, the latter being, as is claimed, inconsistent with bronchial obstruction. The increased volume of the lung will perhaps account for the fixedness of the diaphragm, assuming this to be a clinical fact. That a spasmodic obstruction of the bronchi should be overcome by expiration rather than by inspiration may be, *a priori*, reasonable, but this idea should give way before clinical facts. The dry bronchial râles which are undoubtedly present, forming a marked feature of the disease, demonstrate bronchial obstruction; and the complete disappearance of these râles, together with that of the symptoms of the obstruction in some cases, as an effect of certain remedial agents, such as the inhalation of chloroform, is proof that the obstruction proceeds from spasm.¹

A later theory, by Weber (1872), attributes the obstruction in great part to a swelling of the mucous membrane in the smaller bronchi from dilatation of the blood-vessels caused by a vaso-motor nervous influence. This theory was advanced many years ago by Beau in France. It does not do away with spasm, but attributes to the swollen condition of the membrane a certain measure of obstruction. This theory is not devoid of substantial support from clinical facts. It is consistent with the frequent occurrence of more or less expectoration coincidently with relief of the asthmatic condition, and it serves to explain the not infrequent existence of obstruction notwithstanding the employment of treatment for the relief of spasm. That it is a pathological element of the disease is highly probable, but that it is an effect of the bronchial spasm, as held by Biermer and Trousseau, is perhaps the most rational explanation of its occurrence.

According to Curschmann, many cases of asthma are due to a peculiar chronic affection of the small bronchi, which he designates as *bronchiolitis exsudativa*, and which is characterized by the appearance in the sputum of the spiral structures already described. This affection is often hereditary. The immediate cause of the asthmatic paroxysm Curschmann believes to be bronchial spasm induced by the bronchiolitis.

CAUSATION.—The occurrence of asthma involves a peculiar susceptibility in the bronchial muscular fibres to take on spasmodic action. This susceptibility does not exist in all persons. It constitutes a predisposition to the affection which characterizes certain constitutions. The majority of mankind, no matter to what influences they may be exposed, never have this affection. The predisposition may be transmitted by inheritance. Of those who become asthmatics so large a proportion have had parents or progenitors who manifested the same peculiarity of constitution that there must be admitted to be, in some cases, an innate and inherited predisposition. The fact of its being congenital is also shown by the occurrence of the affection not infrequently in early childhood and infancy, independent of any appreciable external causes. Whether the peculiar susceptibility be always congenital, or whether it be acquired in a certain proportion of cases, it is impossible to say. It is not proof against an innate idiosyncrasy that the affection frequently does not occur until after youth, and is sometimes deferred until old age, and that it follows some other pulmonary affection, such as whooping cough, bronchitis, or measles.

¹ For a fuller exposition of the doctrine of Wintrich the reader is referred to the article by Riegel in *Ziemssen's Cyclopaedia*, Am. ed., vol. iv. For its refutation in *extenso*, vide paper by Biermer, "Ueber Bronchial-asthma," in *Volkmann's Sammlung klinischer Vorträge*, 1870; see also the classical work by Salter, *On Asthma: its Pathology and Treatment*, Philadelphia, 1864.

The etiological connection of asthma with nasal polypi and other morbid conditions seated in the Schneiderian membrane, especially hyperplasia of the erectile tissue covering the inferior turbinated bones, and also with affections of the throat, has recently given rise to discussion. Making allowance for the error of considering the embarrassment of respiration from obstruction of the nasal passages as constituting asthmatic dyspnoea, clinical facts have been reported which show that in some cases true asthma may be produced by a reflex influence originating in the membrane of the nose and throat. This is true of local affections elsewhere, always assuming the existence of an asthmatic predisposition as an essential element in the etiology. The term "nasal asthma" used by some late writers denotes only that in a person whose bronchial muscular fibres are liable to spasm, as an individual idiosyncrasy, certain local conditions within the nostrils may excite an asthmatic paroxysm.¹

For the development of the affection, certainly in most cases, in addition to the predisposition, exciting causes are requisite. The exciting causes are various, and the facts with regard to these show in some persons a remarkable susceptibility to particular agencies which upon most persons produce no morbid effect. A striking illustration of an idiosyncrasy in this regard is the variety of the affection commonly called *hay asthma*. The emanations from newly-mown hay produce in some persons coryza, bronchitis, and asthma, and the latter affection may never occur save when produced by this particular cause. The term *hay asthma*, however, is applied to cases occurring exclusively during the summer season, although the exciting cause may not proceed from hay. We meet with persons who suffer for a certain period during the summer months with asthma, associated with coryza and bronchitis, and during the remainder of the year they are entirely free from the affection. Sometimes the annual visitations in successive years occur precisely on the same date, and the duration is always about the same. For example, a medical friend of the author is attacked early in September of each year with coryza and bronchitis, and subsequently paroxysms of asthma occur during the night. He continues to suffer from the former affections and the nightly recurrence of the asthma for six weeks. The affections then disappear, and except during the period just stated his health is excellent. Relief and exemption are obtained by removing at the period when the affections occur to a situation devoid of, and distant from, vegetation. On going to sea the affections are sure to disappear after sailing a certain distance from land.

The affection known as "hay asthma" or "hay fever," first described by Dr. John Bostock in 1819 under the name *catarrhus æstivus*, has been studied, as it occurs in the northern part of this country, by Dr. Morrill Wyman,² and more recently by Dr. George M. Beard. The latter gives the results of an analysis of 200 cases.³ According to Dr. Wyman, there are two forms of annually-recurring bronchial inflammation (*catarrh*) in persons with a peculiar idiosyncrasy. The first is often called the "rose cold" or "June cold," beginning in the latter part of May or early in June and continuing until early in July. This corresponds with the affection known in England as "hay asthma" or "hay fever." The other form is called by Dr. Wyman *catarrhus autumnalis*, or autumnal catarrh. In this form the affection begins

¹ For a full discussion of the several theories of the causation of asthma by Curschmann, Riegel, Donders, A. Fränkel, B. Fränkel, Hecker, Schmidt, Lazarus, Liebig, and Unger, see *Verhandlungen des Congresses für innere Medicin*, Vierter Congress, 1885. In this country Dr. John N. Mackenzie, Dr. William H. Daly, Dr. John O. Roe, and others have contributed papers on this subject. (Vide *System of Medicine by American Authors*, article by Dr. W. H. Geddings, vol. iii. 1885.)

² *Autumnal Catarrh (Hay Fever)*, New York, 1872.

³ *Hay Fever, or Summer Catarrh*, New York, 1876.

generally in the third or fourth week of August, and ends in the latter part of September or in October. It rarely if ever continues after the occurrence of black frost. Asthma occurs in a certain proportion of cases only. The local symptoms denote irritation and subacute inflammation of the nasal and bronchial mucous membranes, together with some febrile movement and more or less constitutional disturbance. The affection appears not to exist in the Southern States or in the colder regions of Canada. Dr. Wyman has collected a considerable number of cases showing that relief may be obtained by going to certain parts of the White Mountain region, Mount Mansfield in Vermont (one of the Green Mountains), and the Adirondack Mountains in the State of New York.

Dr. Beard's cases show that the affection occurs in July as well as in May, June, and August, but less often than in the latter months; also, that the Southern States and Canada are not exempt from the disease, but that its occurrence is rare. It is a rare disease west of the Mississippi, either north or south. It is undoubtedly caused by the inhalation of some agent connected with vegetation, and probably this agent is the pollen from grass, flowers, and trees. The same cause evidently is not alike involved in all cases. The idiosyncrasy in some persons relates to emanations only in May or June, and in others only to those in August; and of those who have the predisposition some are affected at a particular place at a particular time, and others at the same place and time are not affected. The vegetable emanations, therefore, must be derived from different sources. The discovery of the sources of the causation in a certain number of cases will not apply to other cases. Assuming the morbid agent to be the pollen from plants, the idiosyncrasy in different persons has relation to different plants. The fact that removal during the summer and autumnal months to certain situations secures exemption from the disease to some and not to others is thus intelligible. Dr. Beard's observations give evidence of heredity as involved in the peculiar idiosyncrasy.

A curious idiosyncrasy is exemplified in the author's personal experience. This consists in the production of coryza, bronchitis, and asthma by an emanation from feather beds or pillows. Repeated attacks on sleeping away from home, especially in inns and steamboats, had occurred before the source was discovered. All feather pillows, and even feather beds, do not furnish the special emanation, and the circumstances on which the latter depends I have not ascertained. The poisonous principle is not connected with the odor which is sometimes perceived. I cannot determine beforehand whether a strange bed will excite an attack or not. If the feathers be of the (to me) poisonous kind, shortly after retiring labored respiration, cough, and wheezing begin, and progressively increase until I am obliged to get up, when the difficulty passes off in a few hours, leaving a little bronchitis, which continues for a day or two. I have never experienced the least degree of asthma except as a result of an emanation from feathers.

Dr. Richard M. Crane of Hagerstown, Md., has communicated to me a case under his observation in which attacks of asthma were distinctly traced to sleeping beneath a feather bed made of duck feathers. The cause was not ascertained until after four years of suffering from the affection. It had not existed previously, the patient being fifty years of age, and there was no return of the affection after an ordinary feather bed, made of geese feathers, was substituted for the bed which furnished the causative emanation.

Inhalation of the powder of ipecacuanha in some persons produces similar effects. Several examples of this idiosyncrasy have been reported. On relating my own experience at a meeting of a medical society on one occasion, a member of the society gave an account of a case in which the same effects were produced by an emanation from the body of the horse, so that

the person was debarred from riding or driving on that account. I have recently heard of another case of this kind. Beard cites other instances. Salter gives several examples in his work on asthma. Asthmatic attacks are sometimes brought on by emanations from the bodies of other animals, as the cat, rabbit, etc.

In persons subject to asthma the paroxysms are liable to be induced by a variety of exciting causes, but individual cases differ as regards a particular susceptibility to certain of these causes. In some cases the inhalation of dust is particularly likely to bring on an attack. I have known a patient specially susceptible to the dust of grain and that arising when carpeted rooms are swept. The fumes of burning sulphur produce asthmatic breathing in those subject to the affection. Indigestion in some cases proves an exciting cause oftener than anything else. Some can refer paroxysms frequently to constipation. Salter relates a case in which the application of cold to the instep was sure to provoke an attack. Mental emotions sometimes act as an exciting cause. Occasionally the paroxysms are habitually connected with the menstrual function.

In the great majority of the cases of asthma, bronchitis coexists. In a certain proportion of cases the bronchitis is constant or habitual, and the frequency of the paroxysms depends in a measure on the bronchitis; for if the latter affection be relieved or removed the asthmatic attacks become less frequent. The susceptibility to the exciting causes of spasm is increased by the existence of bronchial inflammation. In other cases the attacks of asthma occur whenever bronchitis or a common cold occurs. Finally, climatic influences are involved in the causation, for it is a matter of frequent observation that the same persons are much more liable to recurrences in some situations than in others. It is also a matter of common observation with some asthmatics residing in a locality in which they are subject to frequent recurrences that atmospherical changes are likely to induce an attack.

Asthma occurs more frequently in males than in females, the proportion being as two to one. In the majority of cases it is developed prior to twenty years of age. It occurs not very infrequently in infancy.

DIAGNOSIS.—The diagnosis in well-marked cases is not difficult. The features of the asthmatic paroxysms are quite distinctive. First paroxysms occurring in young children may occasion some perplexity, but with proper knowledge and care the disease should not be confounded with other affections. Capillary bronchitis is distinguished by the frequency of the respirations, the acceleration of the pulse with more or less fever, and the diffusion over the chest of the subcrepitant râle. In asthma the respirations are not accelerated, but labored, the pulse is not notably frequent, and the dry bronchial râles are abundant. The dyspnoea incident to diseases of the heart often goes by the name of asthma, but the breathing in this form of dyspnoea is not labored, especially the expiratory acts, and accompanied by wheezing, as it is in asthma, and the difficulty in breathing is more or less habitual. Moreover, heart lesions adequate to the production of dyspnoea are determinable by physical signs. Asthma and cardiac lesions, however, may be associated. If asthma have existed for some time, it is usually associated with emphysema, and this association is diagnostic; yet it is to be borne in mind that emphysema sufficient to occasion dyspnoea, which may become greatly increased with a fresh occurrence of bronchitis, may exist without asthma; in other words, the dyspnoea due to emphysema and coexisting bronchitis is not properly called asthma. In addition to the abundance and diffusion of the dry bronchial râles, the physical signs during a paroxysm are enlargement of the chest in its upper and anterior regions, with diminished respi-

ratory movements, vesiculo-tympanic resonance on percussion, and suppression of the respiratory murmur. I have met with instances repeatedly of laryngeal spasm that have been considered as asthma. The differential points are, however, distinctive. In laryngeal spasm the inspiration is slow and labored. In asthma the labor and slowness are in the expiration. The former has been well termed inspiratory, and the latter expiratory, dyspnoea. Laryngeal spasm is accompanied by stridor referable to the larynx, and the latter moves up and down with inspiration and expiration. The dry bronchial râles and the other physical signs referable to the chest are wanting if there be only laryngeal spasm.

PROGNOSIS.—A paroxysm of asthma, however severe or protracted, involves no immediate danger to life. Formidable as may appear an attack of great severity, and intense as is the suffering, it is doubtful if a fatal termination ever took place. In view, however, of the suffering, the tendency of the disease to become confirmed, with an increasing liability to recurrences, its existence must be regarded as a great calamity. If the paroxysms be produced by a particular exciting cause, which, being known, may be avoided, the disease imposes simply more or less inconvenience; but when they are liable to be produced by various causes which cannot be guarded against, it is truly a grievous affliction; and it is calamitous, of course, in proportion to the frequency with which the paroxysms recur and their severity.

Asthmatics are not infrequently long-lived, yet that it may shorten the duration of life cannot be doubted. The labored efforts of breathing in the paroxysms contribute to the development and increase of emphysema. During the paroxysms also, the circulation through the lungs being impeded, the right ventricle and auricle are unduly distended with blood returned by the systemic veins, and hence the disease occasions dilatation of the right side of the heart. The chances of long life are lessened by these lesions. Moreover, if the paroxysms be frequent and severe they can hardly fail to impair the vital powers and diminish the ability to resist other diseases. If asthma secure, to a certain extent, exemption from pulmonary phthisis and pneumonitis, this advantage is perhaps overbalanced by the fact that pneumonitis, when it does occur, is likely to prove fatal, and that the supervention of a severe attack of bronchitis may destroy life.

TREATMENT.—The management of asthma embraces—*first*, the treatment of the paroxysms; and *second*, the treatment in the intervals.

During a paroxysm the objects of treatment are to lessen the suffering and bring the paroxysm to an end as speedily as possible. The measures for these objects have reference to spasm as the essential pathological condition. The measures to relieve spasm are various, each of which proves efficacious in some cases and not in others. Frequently the past experience of the patient is the best guide as to the particular measure which will be most likely to afford relief. In cases of asthma unaccompanied by bronchitis a full opiate is sometimes quickly and completely successful; but in the larger proportion of cases it will not succeed in cutting short the paroxysm or in affording marked relief. [One of the best internal remedies is chloral hydrate, which must, however, be given in full doses to produce an effect. From 20 to 30 grains should be given at one dose, and repeated in half an hour if the benefit from the first dose is not marked. It must be employed with circumspection, especially in long-standing cases in which the heart is functionally weak.—H.] Of other narcotics, stramonium is one which should be tried. The usual mode of administration is to smoke the dried leaves or the fibres of the root either in a pipe or prepared as a cigarette. This measure in some

persons acts like a charm, and may be confidently relied upon as a prompt and effectual mode of obtaining relief; but in the great majority of cases it either produces no effect or merely mitigates the severity of the paroxysm. [The smoke, instead of being immediately ejected from the mouth, should be inhaled into the lungs.—H.] Asafœtida, dracontium or skunk-cabbage, and Indian hemp are sometimes efficacious. The ethers, given internally, are to some extent useful as palliatives, and occasionally they produce complete relief. Belladonna is sometimes signally efficacious, given as recommended by Salter and Ringer—namely, 10 minims of the tincture repeated every two or three hours unless disturbance of vision be produced. The bromides in full doses sometimes afford marked relief. A paroxysm is sometimes made to abort by a full dose of quinia—from 20 to 30 grains to an adult.

Marked relief is frequently obtained and the paroxysm is sometimes cut short by nauseant remedies—namely, antimony, ipecacuanha, lobelia inflata, and common tobacco. The two remedies last named are especially efficacious in a certain proportion of cases. The common tobacco will be more likely to be successful if the patient be not accustomed to its use. With a view to the relief of the spasm these remedies need not be carried to the extent of producing vomiting; if not effectual when nausea is induced, it will be useless, if not injurious, to push them farther. I have known a paroxysm to be arrested at once by bloodletting, but this is a measure too potent to be employed, except occasionally in persons who are robust and full-blooded.

The inhalation of the vapor of ether is often an effective measure of treatment. Not infrequently the paroxysms are completely controlled by it, the patient passing in a few moments from a condition of great suffering into one of ease and comfort. These cases are among those which afford the most striking examples of the resources of practical medicine. The dry bronchial rales, which before the inhalation were loud and universally diffused over the chest, sometimes disappear as soon as complete relief is procured by the inhalation—a fact proving conclusively the existence and the cessation of spasm. Unhappily, this measure, like the others, is efficacious only in a certain proportion of cases. It should be tried always, provided there be no circumstances to contraindicate it. The inhalation of chloroform is often successful, but in view of danger ether is always to be preferred. The inhalation of the nitrite of amyl affords temporary relief, and in some instances arrests a paroxysm. Four or five drops may be inhaled from a handkerchief. Iodic ether or iodide of ethyl is recommended by Thorowgood as highly useful in some cases. Ten drops may be inhaled three or four times daily. This remedy may be conveniently inhaled by dropping it on a piece of patent lint held in the palm of the hand.¹

The vapor of arsenious acid is to be included among the remedies which are useful administered by inhalation. Arsenical cigarettes have been employed with success, each cigarette containing from a half a grain to a grain of the acid.²

The inhalation of compressed air is recommended by German authors. Trousseau found the inhalation of the vapor of ammonia useful in some cases. Duclos succeeded in sometimes arresting a paroxysm by the application of aqua ammoniæ to the fauces by means of a probang. Others who have made trial of this measure have found it in some cases to succeed, but in other cases to increase the dyspnœa.³ Dr. Monell states that he has succeeded in obtaining relief in an attack of asthma by prolonging as far as

¹Vide *Lettsomian Lectures on Bronchial Asthma*, 1885.

²*Ibid.*

³The tincture of quebracho is recommended by Penzoldt and others in asthma and other diseases attended by dyspnœa.

practicable the expiratory act, then waiting as long as possible before inspiring, and retaining the air at the end of the inspiration as long as possible; this plan being continued for fifteen minutes. He states that he has repeatedly obtained immediate relief in this way, and that he knows of several cases in which the plan has proved successful.¹

It is hardly necessary to say that if there be ground to suppose the attack to have been brought on by overloading the stomach or by constipation, an emetic or a cathartic is indicated; and of course the patient is to be removed from the action of any known exciting cause, such as the emanations from hay, feathers, etc. The apartment should be large, high, and airy. Warm and stimulating pediluvia afford some relief. Strong coffee, taken hot, is generally useful as a palliative. It may be rendered more efficient by adding two or three grains of the citrate of caffeine. Another palliative measure which sometimes proves to be curative is to be added. This consists in diffusing throughout the apartment the fumes of burning nitre-paper—that is, bibulous paper dipped in a saturated solution of the nitrate of potassa and dried—or by burning pastilles prepared for that purpose. Some patients find great relief from this measure, and occasionally the paroxysms are arrested by it.

The treatment in the intervals has for its object prevention of the paroxysms. The removal of the predisposition would be the most effectual mode of accomplishing this object. This, however, is not to be expected; and the object is to be attained by measures having reference to circumstances which increase or act upon that susceptibility of the bronchial muscular fibres constituting the predisposition to the affection.

When, owing to a peculiar idiosyncrasy, paroxysms are excited by a particular cause, such as emanations from hay, feathers, etc., avoidance of exposure to the cause, if possible, is obviously indicated. It is doubtful if any remedy will produce insusceptibility to the action of the particular cause or secure exemption so long as the exposure to the cause continues. In the cases of the so-called hay asthma which have come under my observation a great variety of remedies have been tried, but all without much avail. The patient must either endure the continuance of the affection for several weeks, or seek a situation where he is not exposed to the exciting cause. Inasmuch as the cause of this variety of asthma enters the air-passages by the nostrils, and occasions coryza before it reaches the bronchial tubes, the attempt has been made to neutralize it by topical applications within the nostrils. Liquid injections or atomized fluids have been employed for this purpose. Helmholtz found in his own person that a solution of quinia injected into the nostrils was preventive of effects other than the coryza; and this result has been obtained in some other cases. This treatment has, however, much oftener failed than succeeded. [A rather questionable palliative for the coryzal symptoms of hay fever is a solution of cocaine hydrochlorate (gr. iv ad ℥j) applied directly to the nasal passages. The application may be made by means of a probe to the end of which a little absorbent cotton is attached. The probe should be passed along the floor of the nares and other sensitive nasal surfaces until it comes in contact with the posterior wall of the pharynx. The relief obtained by this application is immediate and lasts for a variable period, so that, if it be repeated two or three times daily, the patient may be kept in comparative comfort. This method of treatment is open to the objection of possibly causing vaso-motor paralysis and “relaxed nose,” and to the more serious criticism of possibly leading to the cocaine habit. In my own experience I have not seen the cocaine habit acquired in this way by genuine sufferers from hay fever. Atropia given internally has afforded

¹ N. Y. Med. Record, Aug. 15, 1866.

relief from excessive nasal sensitiveness and flow of mucus, and it seems further to have the power of reducing the systemic disturbance and nervous susceptibility to the specific irritant. It should be given cautiously, beginning with a dose of $\frac{1}{800}$ grain, which may be repeated every half hour until incipient dryness of the mouth appears.—H.]

Recent observations having shown that paroxysms may be excited by polypi and other affections of the nose, and by affections of the pharynx, appropriate local measures of treatment are to be directed to these situations, and in general terms any existing local affection which may be suspected of having a causative relation to the asthmatic paroxysms should, if practicable, be removed.

In a large proportion of the cases of asthma the liability to paroxysms is more or less increased by the existence of habitual or chronic bronchitis. The relief or cure of the latter affection in these cases is the immediate object of treatment. The iodide of potassium or of ammonium should always be tried. I have known patients who were rendered comparatively comfortable as regards the recurrences of asthma by the use of this remedy. In small or moderate doses it may be continued indefinitely without any apparent injury. I have known from 5 to 10 grs. to be taken most of the time during four or five years, the patient finding that thereby he was protected against a recurrence of the paroxysms. The remedy will be useful in proportion to its curative effect on the bronchitis; it is, however, useful in some cases in which the coexisting bronchitis is slight and when no apparent effect upon the latter is produced. The hydriodic acid has proved in some cases as effectual as the iodides. In the treatment of asthma, as of chronic bronchitis without asthma, the doses of the iodides may be gradually increased so as to amount to 50 or 60 grains per diem. The bromides are serviceable in certain cases, and they are well borne by some who cannot take the iodide of potassium without unpleasant effects. The chlorate of potassa is sometimes useful, and the other measures indicated in cases of chronic bronchitis may be employed. The arsenical medication—that is, arsenic in small doses continued for a considerable period—has been found in some cases highly useful. The same is to be said of sulphur.

If measures addressed to the bronchitis prove ineffectual, or if the paroxysms recur when bronchitis does not coexist, and they be not referable to particular causes which may be avoided, nothing is to be depended on but change of residence. And it is probable that most asthmatics may find some place in which they will be comparatively if not entirely free from the affection. Facts showing the immunity obtained by change of residence are remarkable as illustrative of an apparent capriciousness of this affection. Persons residing in the country often find relief by living in cities or large towns. A change from the most salubrious part of a city to a part where the atmosphere is smoky and insalubrious as regards the general health sometimes secures exemption from the affection. A change of apartments from one story to another or to a different exposure has been known to prove effectual. I have known a patient to suffer nightly from a severe attack directly on the seashore, whereas the nights were passed comfortably a mile inland. There are no fixed laws with respect to the best climate or situation for asthmatics; and each case has its own law, which is to be ascertained only by experience. In beginning trials of change of residence, a place should be selected in which the climatic influences are the opposite of those belonging to that in which the patient resides; that is, if the residence be in the country, the city may be tried, and *vice versa*; if on the seashore, an inland situation, and *vice versa*; and so with regard to temperature, moisture, elevation, etc. The principle to be acted on is, that there is a place in which each

martyr to this complaint will suffer less, and perhaps be entirely free from it, and the plan should be to make repeated trials until the desired spot is found. I could cite from the cases which have come under my observation several in which this plan has proved successful. It is to be enjoined, whenever practicable, as soon as it is evident that other measures will not secure the patient against the suffering incident to the frequent recurrence of the affection.

At the present time, in this country, the climate of Colorado is regarded as the most favorable for asthmatics. That residents in that climate are rarely affected with asthma, and that persons who suffer from the disease generally find relief there, cannot be doubted in view of ample testimony; yet it has happened to me to be consulted in the case of a boy about twelve years of age who had suffered from the disease since early childhood, and who has recently come from Denver, where he had lived from birth. A brief stay, however, in Colorado or elsewhere secures exemption only during the time of sojourn; persistent relief requires a permanent change of residence. Hence it is generally an object with patients to find some place where, aside from exemption from this disease, it is for their interest and happiness to dwell.

Pertussis, or Whooping Cough.

This affection belongs among the diseases of children, but it occasionally occurs after childhood and at all ages. In the cases occurring after adolescence it is important that the physician be prepared to recognize it. The affection has no anatomical characters except those of ordinary bronchitis. Other morbid appearances found after death are due to complications which will be noticed in connection with the clinical history.

CLINICAL HISTORY.—The names of this affection derive their significance from certain characteristics pertaining to the cough. The first or the forming stage embraces a period prior to the appearance of these characteristics. The primary symptoms are those of simple coryza and bronchitis. Frequently during this period there is nothing which denotes the affection to be other than a common cold. But in the majority of cases the cough is more violent, the acts of coughing persist for a longer time, and they progressively increase in duration and violence. There is also more or less febrile movement, which is more marked and continues longer than in ordinary bronchitis. At length the cough becomes distinctly and in a marked degree paroxysmal, and the distinctive features of the affection relate especially to the paroxysms. The duration of this first stage varies from one to two weeks. After the affection has advanced to the second stage, the patient is generally aware for a few moments previous to a paroxysm that it is impending. A child engaged in play suddenly is quiet, and the countenance expresses apprehension and distress. The morbid sensations are those of constriction and an irritation in the larynx and trachea. These premonitions are sufficient to arouse the patient when asleep. The paroxysm is denoted by cough, which is characterized by a series of violent expiratory acts succeeding each other so quickly that the patient is unable to take an inspiration between them. The number of these acts varies, according to the severity of the paroxysms, from six to twenty. A long and labored inspiration then takes place, giving rise to a crowing sound evidently due to spasms of the glottis; this is the whoop which enters into the name of the affection. Another series of coughing expiratory acts succeeds, followed again by the sonorous inspiration or whoop; and these alternate acts of coughing and whooping are repeated

until the paroxysm ends. The contraction of the lungs by the spasmodic acts of coughing interrupts not only inspiration, but the pulmonary circulation, so that an accumulation of blood takes place in the right cavities of the heart. These effects are shown by notable congestion and lividity of the face and turgescence of the cervical veins. Tears flow in abundance. The suffering from dyspnoea is in proportion to the violence and length of the paroxysm. The contents of the stomach are frequently expelled, and at the close of the paroxysm more or less mucous secretion is expectorated. In proportion to the violence and length of the paroxysm the patient is fatigued or exhausted. However severe the paroxysm, there is scarcely any immediate danger either from apnoea or syncope. I have never known of an instance of death in a paroxysm. A medical friend, however, has related to me a case in which the breath was lost, and was restored by resorting to the procedure known as Marshall Hall's ready method.

The paroxysms in different cases differ widely in severity, duration, the degree in which the characteristics are marked, and in frequency of recurrence. When extremely severe they occasion great distress, and serious incidental events are liable to occur. On the other hand, when quite mild they are comparatively trivial. Only one or two of the spasmodic expiratory acts may occur, or they may be repeated so that the paroxysm lasts for several minutes. The whoop is more or less loud and long in proportion to the amount of spasm of the glottis. Although generally present and marked—being, as the name implies, the most characteristic feature of the paroxysm—it is sometimes slight and sometimes wanting. In the latter case the character of the disease has to be determined by other diagnostic features. A few paroxysms only may occur in the twenty-four hours, or they may recur during night and day at short intervals. They may amount to even a hundred within the twenty-four hours. In almost all cases they occur in greater number in the night than during the daytime, and in some cases they occur only at night. Exceptionally they are more frequent during the daytime. The paroxysms which occur in sleep are, of course, not produced by any obvious exciting cause. This may be true of paroxysms occurring in the waking hours, but physical exertion and mental excitement, especially the latter, appear not infrequently to determine the occurrence of a paroxysm. Children are liable to experience a paroxysm whenever a fit of crying takes place. A patient may have a paroxysm on witnessing a paroxysm in another patient, this fact illustrating the power of involuntary imitation.

Various events are incidental to the paroxysms, especially when the latter are severe. One of the most frequent of the incidental events is hemorrhage. Epistaxis is the most common form of hemorrhage. Not infrequently blood flows from the nostrils in more or less abundance with every paroxysm, and, the loss of blood inducing notable anæmia, this favors the persistence of the hemorrhage. Hæmoptysis is an occasional form of hemorrhage. Blood sometimes escapes from the conjunctiva or accumulates beneath this membrane. Trousseau cites a case in which a nævus situated on the face was the seat of hemorrhage with each paroxysm. Blood has been known to be forced from the ears. The primary and chief cause of the hemorrhage is the venous congestion arising from accumulation of blood within the right cavities of the heart. The urine and feces, or both, are sometimes expelled involuntarily during the paroxysm. Intestinal hernia is sometimes produced. Rupture of air-vesicles is an accident which sometimes occurs, giving rise to interlobular emphysema; and the air, finding its way along the areolar tissue connected with the primary bronchi and trachea, may produce emphysema of the neck, and even extend over the entire body.¹ Dilatation of the air-cells, or vesic-

¹Vide case reported by Dr. Wm. P. Northrup, in *Am. Journ. of Med. Sciences*, July, 1883.

ular emphysema, is another incidental event. It is questionable whether it be not due to the bronchitis associated with whooping cough rather than to the violent action of coughing; but the latter doubtless contributes to its production. When the paroxysms recur frequently, and are generally accompanied by vomiting, the system suffers from innutrition. Here is a source of anæmia in addition to the hemorrhages. Convulsions occur in some cases, especially in children, being attributable to the cerebral congestion occasioned by the venous obstruction at the right side of the heart.

In the intervals between the paroxysms, aside from complications or intercurrent affections, the general condition will depend on the frequency of the paroxysms, their severity, and the incidental events. The patient is enfeebled in proportion as the paroxysms are long, violent, and frequent, also in proportion to the amount of hemorrhage and the interference with nutrition by vomiting. The face is pallid in proportion to the anæmia. The veins of the neck furnish the venous hum, and the arteries a bellows murmur. Cephalalgia is a prominent symptom in some cases, arising from cerebral congestion. The febrile movement, which generally exists, in a greater or less degree, during the first or forming stage, as a rule disappears when the characteristic paroxysms are established; that is, in the second stage. If it continue into this stage or if it be reproduced, it is due to an unusual intensity of the bronchitis or to some inflammatory complication. The face is swollen or puffed, and this, with the pallor, renders the appearance quite characteristic. Certain complications are liable to occur which add much to the gravity of the affection. Bronchitis is a part of the affection.

If the affection be uncomplicated, physical exploration of the chest elicits good resonance on percussion, with perhaps the dry or moist bronchial râles. The bronchitis in some cases is unusually acute, giving rise to fever and abundant mucous secretions. Collapse of pulmonary lobules and bronchopneumonia are liable to occur in young children. The occurrence of vesicular emphysema has been already mentioned. The inflammation may extend into the minute bronchial tubes, giving rise to capillary bronchitis. This is denoted by fine bubbling râles diffused over the chest, in conjunction with great frequency of the respirations, notable acceleration of the pulse, and lividity, the resonance of the chest on percussion not being diminished. Pleuritis with effusion is another complication more likely to occur in adults than in children. These several pulmonary complications are rendered severe and dangerous by the recurrence of the paroxysms of whooping cough. Frequently the latter become less violent and frequent when any of the complications just named are developed, so that a premature improvement as regards the paroxysms of whooping cough may be an unfavorable omen. When whooping cough is accidentally associated with some acute disease, such as measles or scarlet fever, the paroxysms of cough, as a rule, become less frequent and violent; these intercurrent diseases interfering with the natural course of the affection. Finally, whooping cough appears to favor the development of phthisis in some cases in which the tuberculous diathesis exists.

The duration of the affection is subject to considerable variation. Exceptionally the affection ends spontaneously in a few days. These cases are infrequent, but the fact that the affection is occasionally of short duration when let alone is to be borne in mind with reference to the supposed efficacy of remedies in abridging or arresting it. It is rare for the affection to end within a period of six weeks. In the majority of cases it continues for a longer period than this, and it sometimes persists for many months. As a rule, it gradually declines before it disappears, the paroxysms by degrees becoming less frequent and severe. Frequently, for a considerable period after the affection has ended, the characteristics are manifested, to a greater or less

extent, whenever a bronchitis or common cold is contracted or cough is excited by any cause. Trousseau states that the affection continues for a long or short period in proportion to the duration of the symptoms prior to the characteristic paroxysms; that is, if the latter are delayed the affection will be protracted, but if they are quickly developed the affection is not likely to last long.

PATHOLOGICAL CHARACTER.—This remarkable affection consists of three pathological elements. Bronchitis is one of these. This is the initial element. It is stated that this element is sometimes wanting, but examples must be exceedingly rare. Another element is fever. This is more or less marked in different cases, but is seldom wanting during the first or forming stage. The fever, as a rule, is out of proportion to the bronchitis, and is therefore to be regarded as not symptomatic, but idiopathic or essential. The most prominent of the three elements relates to the nervous system. This is manifested by the spasmodic expiratory movements in the paroxysms of cough, and by spasm of the glottis giving rise to the whoop. Some have considered the affection as belonging among the neuroses, others have considered it to be an essential fever, and by others it has been considered as a peculiar variety of bronchitis. It is neither of these separately, but collectively they constitute the affection. Dependent, as will be seen presently, on a special cause, the primary, essential pathological condition is general or constitutional, of which the bronchitis and cough are the local expressions.

CAUSATION.—Whooping cough is an infectious disease, and it is communicated by a contagium present in the bodies of those affected with it. It probably originates in no other way. It is highly contagious, and few persons pass through childhood without contracting it. Young infants are liable to contract it. No period of life is exempt from susceptibility to the contagium. The infrequency of the affection after childhood is accounted for by the fact that the great majority of persons experience it before adolescence. Having been once experienced, the susceptibility thereafter ceases. This is the rule, but exceptionally the affection occurs more than once. The exceptions to the rule as applied to this affection are not more frequent than to the rule as applied to other affections in the same category—for example, the eruptive fevers. The average period of incubation is not well ascertained. It is variable, the limits being one and two weeks.

[Various organisms, each supposed to be the infectious agent of whooping cough, have been described by bacteriologists, but, unfortunately, no two of them are alike. The bacillus of Afanassjew is at present the one to which most credit is attached, and chiefly because his bacteriological methods were least open to criticism. Before accepting his conclusions, however, numerous control experiments should be made. Points yet to be determined are (1) whether the normal secretions contain similar organisms; (2) whether the latter exist in other diseases of the respiratory system; and (3) whether the bacillus is a constant accompaniment of whooping cough.—H.]

DIAGNOSIS.—When whooping cough has advanced beyond the first or forming stage and the characteristics pertaining to the paroxysms are well marked, it is recognized without difficulty. The whoop is a diagnostic criterion, but this is sometimes imperfect and even wanting. In these cases the diagnosis is to be based on the occurrence of paroxysms presenting the characters of well-marked whooping cough minus the whoop, on the duration of the affection, and on the fact of known exposure to the infection, together with knowledge of the fact that the patient has not already experienced the affection. The affection may be so mild and short that there is considerable doubt

whether it have really occurred, but such cases are rare. It is desirable to make a probable diagnosis during the first or forming stage; that is, before the disease is fully declared by the characteristic paroxysms. It should be strongly suspected when cough and febrile movement are out of proportion to the bronchitis and unduly persistent. Of course the prevalence of the affection and known exposure are to be taken into account. Attention has been recently directed to the occurrence of ulcerations on either side of the frenum linguae as a diagnostic circumstance. These are produced traumatically by the lower teeth, the tongue being partly protruded during paroxysms of cough. They occur only when, from the violence of the paroxysms, the diagnosis involves no difficulty. They are wanting, of course, in children before the period of dentition.

PROGNOSIS.—Whooping cough is rarely fatal *per se*, yet indirectly it leads to a considerable loss of life. Occurring in the course of other diseases—for example, measles or during the ailments incident to dentition—it may prove a serious affection. A fatal result is generally due to complications, the more frequent and important of which have been stated—namely, capillary bronchitis, broncho-pneumonitis, pleuritis, vesicular and interlobular emphysema, and phthisis. Young children, especially during dentition, are sometimes carried off by convulsions. As regards the affection itself, the gravity and danger are proportionate to the frequency and severity of the paroxysms, the duration of the affection, and the degree of anæmia and innutrition induced by hemorrhage and vomiting.

TREATMENT.—The treatment of whooping cough embraces curative and palliative measures. It must be admitted that there are no known means by which the affection may be arrested. Measures are curative if they abridge the duration of the affection or diminish notably its severity, and there are various remedies which possess more or less curative power.

Emetics were formerly considered as curative, given every other day for the space of a week or longer at the beginning of the affection. They were much extolled by Laennec, who preferred ipecacuanha as the emetic drug. Others have preferred the sulphate of zinc. Trousseau advocates, instead of the zinc or ipecacuanha, the sulphate of copper, given in solution in small doses, according to the age of the patient, the doses being repeated at short intervals until vomiting is produced. In view of the testimony in behalf of the treatment with emetics, its efficacy in some cases cannot be doubted, but owing to its severity it is nearly or quite obsolete in this country. This method of treatment, it is to be borne in mind, is not admissible except early in the career of the affection.

Of other curative remedies, some are addressed to the bronchitis and others to the neuropathic element. A combination of cochineal and the carbonate of potassa, commonly known as the cochineal mixture, has been much employed in this country. This mixture consists of cochineal, half a scruple; of carbonate of potassa, a scruple; and of white sugar, a drachm, in four ounces of water. A dessert-spoonful is to be given three times daily to a child a year old, and the dose increased in proportion as the age is greater. The disease is undoubtedly in some cases favorably modified by this preparation, as shown by diminution of the violence of the paroxysms and of the frequency of their recurrence: these effects of remedies can generally be appreciated when the affection has not already continued sufficiently long to attribute the improvement to a spontaneous decline. It is not easy to determine the fact of the duration being abridged, as the natural duration varies within wide limits. This remedy probably acts upon the bronchitis. Meigs

considers the cochineal as inert, and states that he has found the same benefit from the carbonate of potassa alone, dissolved in syrup of gum and water.¹

Alum, which was recommended highly by Golding Bird, is considered by Meigs as giving more decided and satisfactory results than any other remedy which he has employed. From one to six grains may be given every four hours, the dose being graduated to the age. Dissolved in some form of syrup and water, it is not an unpleasant remedy. This remedy probably exerts its curative effect by acting upon the bronchitis.

Belladonna has been recommended as a valuable curative remedy by many physicians in different countries. Trousseau lays down certain rules with regard to its administration which he deems essential in order to secure its curative efficacy. The dose at first should be quite small—one-tenth of a grain of the extract for a child a year old, and one-fifth of a grain for a patient four or more years of age. The quantity to be taken in the twenty-four hours is to be given in a single dose. The dose is to be gradually increased until its effect upon the severity or frequency of the paroxysms is apparent. It should then be continued steadily without further increase. The action of this remedy is doubtless upon the neuropathic element of the affection. Some have regarded conium, stramonium, and hyoseyamus as not inferior to belladonna in this affection. The leaves of the chestnut tree (*Castanea vesca*) have long had a popular reputation, and many physicians have confidence in their curative effect. The infusion is the form generally used, an ounce of the leaves to a pint of boiling water and given freely.

Strong testimony has been borne by not a few physicians to the curative efficacy of nitric acid. To a tumblerful of well-sweetened water the acid is to be added until the acidity is of the strength of pure lemon-juice; of this a dessert-spoonful is to be given to a child a year old every hour, and a larger quantity over that age.

[Antipyrin is largely employed in the treatment of whooping cough, and has many advocates. It may be given to children of ten to twelve years of age in doses of 2 grains every three hours, and in proportionate amount to younger children. Its employment should be suspended on the first signs of cyanosis or if it gives rise to profuse sweating.—H.]

Since the bromides were introduced into medical practice they have been employed considerably in this affection, and with apparent benefit. These remedies are probably useful as pharyngeal and laryngeal anæsthetics; hence they are addressed to the neuropathic element of the affection.

Other remedies which have been recommended, and which I shall simply name, are tannic acid, asafoetida, arsenic, quinia, chloroform, the oxide of zinc, and ergot. A method of treatment which it was claimed had proved remarkably successful was some years since brought before the French Academy of Medicine—namely, inhalation of the fumes disengaged in the purification of coal-gas. It having been observed that children living in the vicinity of gas-works suffered but little from whooping cough and recovered after a short career of the affection, the effect was tried upon a large scale, and, as stated by Commerege and Bertholles in their reports to the French Academy, with signal benefit to a large proportion. To secure the advantage of this measure patients should inhale the fumes at the place where the gas is purified, for two hours at a time, for twelve consecutive days.² It would appear from the statements by Blache, Barthez, and Roger that this measure is often inefficacious. It is, however, sometimes promptly curative.

Of the different remedies which have been noticed, all are doubtless more or less curative in a certain proportion of cases. It may be doubted if any

¹ *A Practical Treatise on Diseases of Children*, by J. Forsyth Meigs, M. D.

² *Vide American Journal of the Medical Sciences*, April, 1865.

of them ever have a specific effect. They are, severally, useful in some and not in other cases; the degree of the usefulness of each varies in different cases, and with our present knowledge the physician cannot judge beforehand what particular remedy in any individual case will be most useful. Under these circumstances, if those first selected prove inefficacious, others are to be successively tried.

Palliative treatment is important. Relief may be afforded by opiates in small doses if they be well borne, by ethers, and by hydrocyanic acid. The latter remedy is, of course, to be given with great caution. Strong coffee has been found to be sometimes useful as a palliative. The hydrate of chloral has been found to be an effective palliative remedy, but the physician is not justified in incurring risk of the occasional danger attending its use, even in small doses, especially when the patient is a child and the object is simply palliation. Many of the antispasmodic remedies are useful as palliatives; of these, the value of musk in this as in other diseases is perhaps not sufficiently recognized in this country.

Prof. J. Lewis Smith has found the inhalation of carbolic-acid spray decidedly useful in diminishing the frequency and the severity of the paroxysms of cough. Spray from the following mixture was inhaled from the steam atomizer three times daily, from two to five minutes: Acid. carbolic. ʒss, potass. chlorat. ʒij, glycerinæ ʒij, aquæ ʒvj.¹ Prof. Smith calls attention to the apparent effect of the treatment, which of late years has consisted chiefly of palliative and sustaining measures, upon the mortality from this disease. Fifty years ago, in the city of New York the proportion of deaths attributed to whooping cough to the deaths from all diseases was 1 in 76, whereas at the present time it is less fatal than any other severe contagious malady. Inasmuch as this is an infectious disease, and is therefore caused by the presence of a specific micro-organism, a curative disinfectant remedy administered internally or by inhalation may hereafter be discovered. Carbolic-acid spray and the fumes of coal-gas probably act as disinfectants.

Hygienic measures form an important part of the treatment. If there be no complications which interfere with exposure to the open air, this should by all means be advised and enforced. Under proper prudential restrictions the more out-of-door life the better. The diet should be nutritious. If from the frequency of vomiting the system suffer from innutrition, alimentation becomes an important object of treatment. The patient should take food often, and as soon after a paroxysm as possible. The times chosen for giving food should be as remote from an expected paroxysm as practicable, and eating at the most favorable times should be insisted upon despite the absence of appetite. Solid is to be preferred to liquid food, as less likely to be rejected by vomiting. Trousseau states that in some cases patients vomit with the paroxysms which occur in the daytime, and not with those occurring during the night; and in such cases food should be taken freely during the night. The stomach is sometimes made to tolerate food by minute doses of opium. Change of air is sometimes of signal efficacy in modifying the severity of the affection and bringing it to a close.

Hemorrhages, if profuse or recurring frequently, claim hæmostatic measures of treatment.

Complications call for the therapeutical measures appropriate under other circumstances, making due allowance for the effects of this affection on the circulation, the blood, nutrition, and the general strength of the system.

There is no known method of preventing the disease other than by isolation as regards exposure to the contagium.

CHAPTER XI.

PULMONARY HEMORRHAGE.—PULMONARY GANGRENE.—
PULMONARY ŒDEMA.—CARCINOMA.—HYDATIDS.

Pulmonary Hemorrhage.—Bronchorrhagia.—Pneumorrhagia.—Hemorrhagic Infarction.
—Pulmonary Gangrene.—Pulmonary Œdema.—Carcinoma within the Chest.—Hydatids.—Syphilitic Disease of the Lungs.

Pulmonary Hemorrhage.

PULMONARY hemorrhage may have as its source—*first*, the bronchial mucous membrane; and *second*, the parenchyma of the lungs. When from the former source, it is called *bronchorrhagia*, and from the second, *pneumorrhagia*. The source of the hemorrhage also may be exterior to the lungs. The most frequent example of this is the rupture of an aneurismal tumor into a bronchus. Hemorrhage having its source in the pulmonary parenchyma may attend diseases in which the air-cells remain intact and diseases causing destruction of the pulmonary parenchyma, especially pulmonary tuberculosis and pulmonary gangrene.

Bronchorrhagia exists in the majority of the cases in which hæmoptysis occurs. The latter term should be limited to the spitting of blood, and should be applied only to the cases in which pure or unmixed blood is expectorated. It is not properly applicable to sputa streaked with blood in cases of bronchitis, or to blood intimately mixed with mucus and inflammatory products in the rusty expectoration of pneumonitis. A true hæmoptysis is the raising of blood, and blood only. In bronchorrhagia the seat of the hemorrhage is most frequently in the small and terminal bronchi. Hemorrhage from the larynx, trachea, or large bronchi is infrequent. In the rare cases in which the loss of blood has occasioned death it has not been found possible to demonstrate the source of the hemorrhage. The blood probably comes from rupture of capillaries and other minute vessels in the mucous membrane of the small bronchi.

It is important to determine, when blood is ejected from the mouth, whether it comes from the air-passages. It may come from the stomach, from the posterior nares, and from the mouth or fauces. If it come from the stomach, it is ejected by acts of vomiting; it is likely to be commingled with other contents of the stomach; it has the characteristic acid odor of the latter; and it gives an acid reaction, whereas pure blood is alkaline. Coming from the stomach, it usually has a black grumous appearance, due to the action of the gastric acids. In some cases of profuse bronchorrhagia considerable blood may be swallowed and afterward vomited. In a case which I saw in an emergency, the blood coming most profusely from the mouth and nose, the source of the hemorrhage was evidently within the air-passages. Some hours afterward, when the patient was seen by the attending physician, the hæmoptysis had ceased, and a considerable quantity of blood was exhibited which had evidently been vomited. In this case there were both hæmoptysis and hæmatemesis, the latter following the ingestion of blood derived from the air-passages. On the other hand, blood which has flowed into the stomach from the erosion of a large vessel, and is vomited before it becomes mingled with the gastric juice, may retain its bright-red color and its alkalinity. If it come from the posterior nares, it is in the form of dark, solid sputa which are removed by acts of hawking. If it come from the mouth or fauces, the fact

may generally be ascertained by a close inspection of these parts. When it comes from the air-passages, it is raised by acts of coughing, which are generally not violent; the blood rises into the trachea and larynx and is expelled with slight efforts. In the majority of cases the blood is liquid, of a bright arterial hue, and contains air-bubbles in more or less abundance. If, however, the hemorrhage have taken place slowly into the bronchial tubes, and the blood have remained there for some time before being expectorated, it undergoes coagulation and acquires a dark or almost black appearance.

The amount of hæmoptysis varies much in different cases. It is sometimes quite small, only a drachm or so of blood being raised; usually, however, when the amount is relatively small or moderate, several drachms or a few ounces are expectorated. Not infrequently the amount is considerable. It is not rare for patients to lose during an attack of hæmoptysis from half a pint to a pint of blood, and sometimes a much larger quantity. The blood is expectorated with more or less rapidity. The continuous duration of an attack of hæmoptysis may vary from a few minutes to several hours, and even many days; in the latter case, of course, the blood escaping slowly. Occasionally the flow of blood is so rapid that it escapes simultaneously from the nose and mouth, and death by suffocation may result from its accumulation in the air-passages. A single attack only may occur, or attacks may be repeated at intervals varying greatly in duration in different cases. In some cases attacks recur daily or repeatedly during the day for a variable period. In other cases the attacks recur after days, weeks, months, or years. After an attack it is common for the expectoration to be more or less colored with hæmatin for several days. In proportion as it is rapidly discharged it is less frothy than when the quantity expectorated with each act of coughing is small. When the hæmoptysis is rapid and abundant, if the patient be not in advanced phthisis, the bursting of an aneurism should be suspected. The hemorrhage from this source, however, is not always at first abundant and rapid, the opening being for a time too small for the free escape of blood. In cases of phthisis advanced to the cavernous stage the hæmoptysis may be rapid and abundant, leading sometimes to fatal syncope, the hemorrhage being due to the opening of a vessel contained in one of the bands of pulmonary tissue which frequently traverse tuberculous cavities, or to the rupture of the minute aneurismal dilatations which late observations have disclosed in the walls of these cavities.

In the majority of cases bronchial hemorrhage is in some way pathologically connected with pulmonary phthisis, and from the frequency of this connection it is important as a diagnostic symptom of that disease. Not infrequently it is the first event which awakens the attention of patients to the existence of pulmonary disease. In a large proportion of cases it occurs more or less frequently during the progress of phthisis. In a certain proportion of cases it occurs when physical signs do not afford evidence of the existence of phthisis, these signs becoming developed sooner or later after its occurrence. In these cases it is probable that tubercles already exist in the terminal bronchi, and that the hemorrhage is due to a tuberculous ulceration into the blood-vessels in the coats of the bronchi. In many cases of initial hæmoptysis of phthisis tubercle bacilli have been found in the blood or sputum, and in this way valuable aid in diagnosis may be afforded by the examination of the sputum. Hæmoptysis should always excite a strong suspicion of tuberculous disease, yet its significance in this respect was undoubtedly overestimated by Louis in his treatise on phthisis. Louis, having questioned a large number of patients affected with various diseases other than tuberculosis, and finding that spitting of blood had taken place in no instance save after injury of the chest or when the catamenia were suppressed, concluded that this symptom is almost pathognomonic

of phthisis. Since the publication of that work, however, it has been found that cases are not very infrequent in which hæmoptysis is not accompanied or followed by either the symptoms or signs of tuberculous disease. A paper communicated by the late Prof. John Ware contains statistical information of special value with reference to this point.¹ Ware in this paper gave the results of an analysis of 386 cases of hæmoptysis noted in private practice during a period of about forty years. Of these cases, in 62 recovery from the bronchial hemorrhage took place, and the patients afterward were either known to be living in ordinary health or to have died of other diseases having no connection with the existence of tubercles. The length of time during which this immunity continued varied from two to thirty-seven years. In addition to these cases, in 52 a similar complete recovery took place, and, so far as known, there was no development of tuberculous disease; but the entire subsequent history of these cases had not been obtained. Making allowance, in a certain proportion of the cases, for the probable occurrence of small phthisical affections which were arrested and did not return, these facts show that neither the existence of phthisis nor a strong proclivity thereto is to be positively predicated on the occurrence of bronchorrhagia. They show, moreover, that as regards any immediate or remote evils bronchial hemorrhage may be innocuous. These conclusions are corroborated by the facts developed by my own clinical studies relating to phthisis.²

Bronchorrhagia is incidental to certain cardiac lesions, especially those involving obstruction at the mitral orifice. These lesions lead to bronchial hemorrhage by inducing pulmonary congestion. It may occur in connection with morbid conditions of the blood and tissues, which lead to hemorrhages from mucous membranes in different situations, as in purpura hæmorrhagica and scorbutus. It occurs occasionally in asthma. It may be produced by violent and prolonged muscular exertions, without the coexistence of any pulmonary or cardiac affection, and it has been observed to occur from muscular exertions, not excessive, if conjoined with diminished pressure of the atmosphere in elevated situations, as in ascending high mountains. It may be produced traumatically by injuries and wounds of the chest. It may occur as a secondary hemorrhage when the menses are suppressed. Well-authenticated cases of this kind have been reported, but they are exceedingly rare. I have met with a striking example, the hæmoptysis occurring regularly for the four years following the suspension of the menses, and no other pulmonary affection either accompanying or following the hemorrhage. The 386 cases analyzed by Ware did not include a single case in which the hemorrhage could be considered as compensatory for the menses. Exertion and mental excitement, by their effect on the circulation, may act as exciting causes if, from pulmonary disease or other circumstances, a predisposition exist; but clinical observation shows that in the larger proportion of cases the hemorrhage takes place without any apparent exciting cause. It takes place frequently during the night-time.

The occurrence of hæmoptysis generally occasions much alarm and anxiety. If patients be seen at the time, the nervous agitation and disturbance of the circulation, which are often present, are attributable in a great measure, if not altogether, to the mental condition induced by the attack. The first duty of the physician is to endeavor to remove needless apprehensions from the mind of the patient. Hæmoptysis proceeding from bronchial hemorrhage may destroy life either by suffocation or by exhaustion from the loss of blood, but the cases are so rare that the danger of fatal consequences is

¹"On Hæmoptysis as a Symptom," by John Ware, M. D., etc., *Publications of the Massachusetts Medical Society*, 1860.

²Vide work on *Phthisis*, 1876.

scarcely to be considered. The physician may assure the patient of the absence of any immediate danger; and, in general, the hemorrhage does not lead to any evil results. It is suggestive of the existence of phthisis, but aside from its symptomatic significance it affords little occasion for alarm. So far from favoring a tendency to tuberculous disease, there is ground for the conjecture that it is sometimes preventive of that disease; and when it occurs in connection therewith, clinical observation shows that it exerts no unfavorable influence on the progress of the disease, but, on the contrary, its influence seems, as a rule, to be favorable.

In exceptional cases bronchial hemorrhage apparently leads to either the development or an increase of pulmonary symptoms, together with more or less fever. The immediate local and constitutional sequences are sometimes exceedingly grave, and death may take place within a few days. I have met with several cases in which, dating from an hæmoptysis, rapid breathing, dyspnoea, frequency of the pulse, and a high temperature occurred, the cases ending fatally after a certain number of weeks or months. Such cases, however, are rare. Niemeyer held the opinion that the retention of blood in the bronchi and air-cells after an hæmoptysis excites inflammatory changes which lead to cheesy degeneration and phthisis. He considered phthisis to be the result, and not the cause, of this initial hæmoptysis. Experiments, however, have shown that the presence of blood in the bronchi and air-cells may excite a lobular, but never a caseous, pneumonia or tuberculosis. The view of Rindfleisch, therefore, is more probable, that the hemorrhage may hasten the development of phthisical symptoms by occluding the bronchi and causing atelectasis and lobular pneumonia, but that in these cases tubercles are already formed before the hæmoptysis and stand in a causative relation to it. In cases of death directly following a profuse hemorrhage the bronchial tubes have been found, post-mortem, filled with clots, and the obstruction of respiration caused by these doubtless was the immediate cause of death. Blood-casts of the bronchial tubes are sometimes expectorated.

The measures of TREATMENT directed to the hæmoptysis must have reference to the profuseness or otherwise of the hemorrhage and the associated symptoms. Venesection heretofore has been frequently employed. This, however, is indicated only in cases in which the patient is full-blooded or the pulse abnormally strong; and such cases are comparatively few. Even in these cases, unless the escape of blood be unusually rapid and abundant, a saline purgative and sedative remedies are to be preferred to bloodletting. If the hemorrhage be profuse and persisting, cold may be applied to the chest, as in hemorrhages in other situations. This may be done by means of compresses wet with iced water or with ether, which latter refrigerates by its rapid evaporation. The application of the ice-bag to the chest has been recommended, and I have resorted to it with apparent success and without any untoward consequences. Revulsive measures may be employed, consisting of stimulating pediluvia, sinapisms, and dry cupping. To diminish the amount of blood returned to the heart, temporary ligation of the extremities may be resorted to. I have witnessed a prompt arrest of the hemorrhage by this measure. A popular remedy is common salt, which usually has been freely given before patients come under the care of the practitioner. Its efficacy is doubtful, but its use serves to occupy the attention of the patient and friends until medical advice is obtained.

In all cases quietude of body is to be enjoined, the use of the voice is to be restrained, the apartment should be kept cool, the head and shoulders should be raised, the diet should be bland or unstimulating, drinks should be cold, and small pieces of ice may frequently be taken into the mouth. These measures are doubtless of more or less importance, yet I have repeatedly

known patients who, having become accustomed to attacks of hæmoptysis, paid little or no attention to it, and kept about their ordinary pursuits as usual, without apparently increasing or protracting the hemorrhage by this course. I have known a lecturer continue the daily use of the voice in public speaking without any apparent injury. The measures just enumerated are often continued too long, patients being anxious to prevent a recurrence of the hemorrhage after it has ceased. They may be assured that moderate exercise out of doors, a nutritious diet, etc. will not be likely to reproduce an attack.

Cough, if present, should be quieted by some form of anodyne. Anodyne remedies are also generally indicated by the excited condition of the nervous system. If the hemorrhage be slight or moderate, as a rule nothing is required in addition to these remedies and such hygienic regulations as may be deemed prudent. If, however, the hemorrhage be considerable and prolonged, hæmostatic remedies are to be employed. Of these, probably ergot is the most efficient. From one to two drachms of the fluid extract may be given hourly or half hourly according to the urgency of the indication, the doses being repeated for several hours if required. *Krameria* and tannic or gallic acid are also efficient vegetable astringent remedies. Of the astringents belonging to the mineral kingdom, the acetate of lead has long been considered valuable in this application. The most efficient preparations of this class, however, are the persulphate and pernitrate of iron. The inhalation of astringent remedies in the form of atomized liquids or spray has been found effective for the arrest of hemorrhage. For this purpose solutions of alum, tannin, and the perchloride of iron may be employed.

I have met with a few cases of persistent bronchial hemorrhage which claim a separate notice. The hemorrhage in these cases was slight, but it continued for a long period, without other evidence of pulmonary disease. It was not referable to disease of the heart, to suppression of the menses, or to any appreciable cause. Moreover, the hemorrhage was confined to the bronchial mucous membrane, and the blood did not come from either the mouth, throat, or nasal passages. The hemorrhagic expectoration was not pure blood, but a thin, bloody liquid. I have notes of three such cases. In two of these cases, after expectorating almost daily more or less of a sero-sanguinolent liquid during several months, recovery took place under the use of tonics and invigorating hygienic measures. In the third case the hemorrhagic expectoration continued for six years, during which period the patient, a young woman, from time to time came under my observation. Repeated examinations of the chest by others as well as myself failed to discover any positive signs of pulmonary disease. During the greater part of the long period just named there was daily more or less expectoration of liquid containing blood-coloring matter, the quantity being always small. Associated with this symptom were anæmia and hysterical ailments. Aside from these nothing was discoverable. The subsequent history of this case is unknown.

Pneumorrhagia, or the extravasation of blood into the air-cells, and frequently also into the interstitial tissue, is commonly known as pulmonary apoplexy. There would be no impropriety in this use of the term apoplexy if we adopted the custom of French writers of expressing by it extravasation of blood in any situation; but with us when applied to a cerebral affection it includes cases in which there is no extravasation of blood, and it is not customary to apply it to extravasation elsewhere than in the brain, spinal cord, and lungs. The name pneumorrhagia is to be preferred.

Extravasation of blood into the pulmonary parenchyma may occur either with or without laceration of the pulmonary tissue. Extravasation with

destruction of pulmonary parenchyma is called *diffuse* pulmonary apoplexy or *diffuse* pneumorrhagia. In *circumscribed* pneumorrhagia or hemorrhagic infarction the blood is in the air-cells and interstitial tissue, but there is no rupture of the lung-tissue. Hemorrhage with laceration of the pulmonary tissue is most frequently the result, either of traumatism, such as stab-wounds and gunshot injuries of the lungs, or of the rupture of an aneurism adherent to the surface of the lungs. The blood lies in a cavity of which the walls consist of torn lung-tissue. The tissue surrounding the cavity is usually diffusely infiltrated with blood. There may be at the same time rupture of the pleura followed by a discharge of blood into the pleural sac. This diffuse hemorrhage, with destruction of the pulmonary parenchyma, is less frequent, but more serious, than the circumscribed form.

In cases of bronchial hemorrhage the blood may be drawn by inspiration into the air-cells and produce the appearance of hemorrhagic infarction. Blood may be inspired likewise into the air-cells in cases of wounds of the lingual artery or of suicide by cutting the throat. Hemorrhage from phthical cavities and from gangrenous disintegration of the lungs is noticed when treating of these affections. Excluding these conditions, the most important causes of pneumorrhagia without laceration of pulmonary tissue are active and passive congestion of the lungs, injuries and disease of the central nervous system, especially cerebral hemorrhage, diseases attended by a hemorrhagic diathesis, as scorbutus, purpura, yellow fever, and acute yellow atrophy of the liver, and either thrombosis or embolism of branches of the pulmonary artery.

The term *hemorrhagic infarction* is applied especially to hemorrhage following embolism of branches of the pulmonary artery, the most frequent and important of the causes just mentioned. These embolic infarctions are firm, dark-red in color, and wedge-shaped, with the base of the wedge toward the surface of the lung and the apex toward the hilum. In the majority of cases the base of the infarction reaches the surface of the lung, the pleura over the infarction being usually coated with a delicate layer of fibrin. These infarctions may be single, but they are frequently multiple. They may occupy the greater portion of a lobe, but usually they are about the size of a walnut or pigeon's egg. They are most common in the posterior portion of the lower lobe. The affected portion of lung is free from air. The microscopical examination shows the air-cells filled with blood and the alveolar septa compressed and infiltrated with red blood-corpuscles. There are fewer nuclei than normal in the walls of the alveoli, in consequence of coagulation necrosis. The tissue surrounding the infarction is congested, oedematous, or solidified with pneumonic products. Emboli may lodge in branches of the pulmonary artery without causing hemorrhagic infarctions. Although the branches of the pulmonary artery do not anastomose with each other, and therefore belong anatomically to the terminal arterial system, blood may be brought to the capillaries of an occluded artery by means of anastomoses with the bronchial artery and other small arteries which enter the lung (Küttner), and by means of surrounding capillaries. In many cases these anastomoses suffice to carry on the circulation in a district, the main artery of which has been obstructed by an embolus; but if the circulation be enfeebled by weakness of the right side of the heart, or if there be obstruction to the flow of blood from the pulmonary veins into the left side of the heart, the anastomoses no longer are sufficient, and a hemorrhagic infarction results within the district the artery of which contains an embolus. Cohnheim's explanation has been generally accepted, according to which the blood in the infarction is derived by a regurgitant flow from the veins leading from the affected district; but according to Litten's experiments the blood is brought

to the capillaries of the occluded artery by the small anastomosing arteries mentioned above and by adjoining capillaries, the pressure in which does not suffice to force the blood into the veins. The blood escapes by diapedesis, and not by rhexis. Infarctions are more frequent in the periphery than in the interior of the lungs, because the anastomoses are fewer and the circulation feebler in the former situation. If life be prolonged, the blood in a hemorrhagic infarction may be in great part absorbed, and only pigmented fibrous tissue, or possibly only a pigmented stain, be left behind.

In the majority of cases hemorrhagic infarctions in the lungs are associated with cardiac disease, especially with mitral obstruction or regurgitation. They appear when the right cavities of the heart have become weakened and dilated and thrombi have formed in the right auricle or ventricle. These thrombi are the source of emboli which are carried into branches of the pulmonary artery. It is possible that thrombi may form in branches of the pulmonary artery in heart disease. Pulmonary infarctions may be the result also of emboli derived from thrombi in the peripheral veins, as in cases of thrombosis of the femoral vein. It is not always possible to demonstrate a source of emboli in cases of pulmonary infarction.

The **DIAGNOSIS** of either form of pneumorrhagia is by no means always easy. Hæmoptysis is of course present when the source of the hemorrhage is bronchial and the extravasation is due to the inhalation of blood into the cells. This symptom is also present in the majority of cases in which the hemorrhage takes place within the cells, but it may be wanting. When present, the hæmoptysis may be either small or abundant; and the amount of extravasation is by no means in proportion to the quantity of blood expectorated. The respirations are hurried and labored in proportion to the extent of lung solidified by the extravasated blood. Dyspnoea and a sense of oppression are also proportionate to the degree in which the respiratory function is compromised. These symptoms, however, are measurably due to the coexisting cardiac lesions when the latter stand in a causative relation to the hemorrhage. Dulness on percussion will be found over a space or over spaces corresponding to the situation and extent of solidification. This may not be appreciable if the extravasation be in the form of small disseminated nodules; but if the extravasation be diffused over a considerable space, the dulness becomes a very significant sign, provided tuberculosis, pneumonitis, and other affections involving solidification can be excluded. A feeble bronchial respiration may be associated with the dulness on percussion, or the respiratory sound may be suppressed over the extravasation. The presence of blood in the cells and smaller air-tubes will be likely to give rise to the subcrepitant, and perhaps to a well-marked crepitant râle within a limited space. These signs, suddenly developed in connection with hæmoptysis and with mitral cardiac lesions, may lead to a diagnosis; but in the cases in which no blood is expectorated a positive diagnosis is extremely difficult if not impracticable.

Circumscribed extravasation, incidental to bronchial hemorrhage, is not necessarily serious; and perhaps it occurs to a limited extent not infrequently in cases of abundant hæmoptysis followed by recovery. If there be no injury of the pulmonary structures and the blood simply infiltrate the air-cells, it may be gradually removed by absorption and expectoration, the normal condition being restored, as after solidification from pneumonitis. If due to embolism, the hemorrhage may lead to gangrene, or the infarcted portions may become the sites of embolic pneumonia and the so-called metastatic abscesses. The latter do not occur unless the emboli contain infectious matter. If these results do not follow, and if the number and size of the spaces in which the extravasation has taken place be not large, recovery may take place. When,

however, the hemorrhage into the air-cells and into the areolar tissue is considerably diffused, the termination is usually fatal and death may take place speedily. Other things being equal, the gravity of the symptoms and the immediate danger are in proportion to the amount of extravasation.

The TREATMENT of different forms of pneumorrhagia must have reference to the symptomatic indications in particular cases, in addition to analeptic and supporting measures.

Pulmonary Gangrene.

Pulmonary gangrene may be defined as death or necrosis of lung-tissue, accompanied by decomposition. It is one of the infrequent pulmonary affections. Its occurrence in cases of lobar pneumonitis and of hemorrhagic infarction has already been referred to. Its most frequent causes are those which either lower the vitality of portions of the pulmonary tissue or favor the introduction into the lungs of decomposing or infectious substances. Among the causes may be mentioned interruption of the blood-current by compression or embolism of the pulmonary or bronchial vessels; infectious diseases, especially those accompanied by the formation of septic emboli; penetrating wounds of the lungs; severe contusions of the chest; decomposition of the contents of bronchiectatic and of tuberculous cavities; the entrance of foreign substances into the bronchi, such as bits of food in attempts to artificially feed insane patients; the ulceration of abscesses and of tumors (*e.g.* cancer of the œsophagus) into the bronchi, etc. Pulmonary gangrene occurs more frequently in males than in females, and also in those whose powers of resistance are enfeebled by alcohol, poverty, bad hygiene, or disease. It sometimes occurs in diabetes mellitus. It may occur as an idiopathic affection in previously healthy individuals; that is, without any apparent cause.

It is presented in two forms, which are distinguished as *diffused* and *circumscribed*. In the circumscribed form the gangrene occurs in sharply-defined spots of variable size, usually between that of a bean and that of a hen's egg. There may be only one gangrenous focus or there may be several foci. They are more frequently situated in the periphery than in the central parts of the lung, and more frequently in the lower than in the upper lobes. The gangrenous spot at first is dark-brown or greenish, dry and friable. Later it undergoes softening, and a cavity is formed, with sloughy walls, containing an extremely offensive greenish or brown fluid holding in suspension shreds of decomposed lung-tissue. The microscopical appearances of the fetid contents of the gangrenous cavities are identical with those of the sputa. The lung-parenchyma immediately surrounding the gangrenous centre is usually in the condition of lobular pneumonia; and not infrequently it is the seat of hemorrhages. The gangrenous process tends to spread peripherally. In the cases in which the disease terminates in recovery the walls of the cavity become cleaned off and free from the adherent shreds of lung-tissue; a kind of pyogenic membrane is formed; and finally, by adherence between the opposite sides of the cavity or by the growth of granulations, the cavity is entirely obliterated, only a cicatrix remaining. In the process of extension of the gangrenous process the blood-vessels are usually thrombosed before they disappear; but sometimes they are opened before they become impervious to the blood-current, and then severe and even fatal hemorrhage may ensue. When the gangrenous patch reaches the surface of the lung, the overlying pleura is covered with a layer of fibrin. Frequently, general pleuritis results, which may be of a gangrenous character. Sometimes the gangrenous focus opens into the pleural cavity, giving rise to pneumo-pyothorax. Thrombi

may form in the veins in the neighborhood of the sloughy centres in the lung. From this source infectious emboli may be carried to the various organs of the body. Intense bronchitis, sometimes of a diphtheritic character, may result from the irritation of the gangrenous matter.

Diffuse gangrene may be secondary to the circumscribed form, or it may be diffuse from the first. The greater portion of a lobe, a whole lobe, or even a whole lung, may be involved. The pulmonary parenchyma is broken down into a putrid, greenish, or blackish pulpy mass, without an evident line of demarcation. It is always fatal.

The SYMPTOMS in cases of gangrene relate measurably to the general condition or to associated affections. The pulmonary symptoms due to the gangrenous condition at first are those which belong to circumscribed pneumonia, consisting of cough, some pain, and accelerated breathing, and after a time an expectoration, more or less abundant, of characteristic appearance and odor. The gross and the microscopical appearances of the sputa have been studied carefully by Traube¹ and by Leyden and Jaffe.² The sputa are of a yellowish, greenish, or brownish color according to the varying amount of pus and of blood present. They emit a penetrating, intensely fetid odor. When fresh they are alkaline, but upon standing become acid. By allowing the expectoration to stand for a while in a glass dish three distinct layers become visible: the upper is frothy, opaque, and of a dirty gray or yellowish color; the middle is clear and watery; and the lower is greenish and purulent, or it may be brownish from admixture with pigment or blood. In this lower layer are shreds of lung-tissue visible to the naked eye, and gray or whitish masses. Microscopical examination reveals granular detritus, pus-corpuscles, triple phosphate crystals, drops of fat, and acicular crystals of the fatty acids, often in bunches. In addition, granular or angular fragments of brown or black pigment, round and rod-shaped bacteria, spiral bacteria, leptothrix breads, and infusoria are met with. The bacteria and fatty drops and crystals are often compacted together into little yellowish clumps visible with the naked eye—the so-called plugs of Dittrich, already described under the head of Fetid Bronchitis. The shreds of lung-tissue seen with the naked eye are of a dirty-gray or black color, and consist chiefly of granular detritus, dark pigment, and bacteria, with occasionally some elastic fibres. Elastic fibres are rarely present, according to Traube, in the gangrenous expectoration. Later observations show that Traube underestimated the frequency with which elastic fibres are found in gangrenous sputa; still, it remains true that the microscopical shreds of lung-tissue frequently found in the expectoration of pulmonary abscess contain many elastic fibres, often marking out the outlines of the alveoli, whereas elastic fibres are more scanty in the sputum of pulmonary gangrene.³

Pulmonary gangrene may be confounded with fetid bronchitis, decomposition in the contents of dilated bronchi and of tuberculous cavities, and with pulmonary abscess. The diagnosis is not to be based upon the gangrenous odor of the breath and sputum alone. In fetid bronchitis and in cases of decomposition of the contents of pulmonary cavities microscopical shreds

¹ *Deutsche Klinik*, 1853, 1859, 1861 *et seq.*

² *Deutsches Archiv f. klin. Med.*, ii. p. 488.

³ According to the experiments of Filehne—"Ueber die Vorgänge bei dem Lungenbrande," *Sitzungsberichte der Phys. Med. Soc. zu Erlangen*, Jan. 11, 1877—in the sputum of pulmonary gangrene a digestive ferment is present capable of dissolving in alkaline solution the elastic fibres and albuminous substances, but not acting on ordinary white fibrous tissue, which may be found in gangrenous sputum when the elastic fibres are absent. Elastic fibres resist putrefactive changes much longer than those induced by digestion.

of lung-tissue are not present in the expectoration; in pulmonary abscess they are often present, but they contain abundant elastic fibres, which are less abundant and are often absent in pulmonary gangrene. Again, pulmonary abscess is not usually accompanied by the fœtor of gangrene.

In cases of circumscribed gangrene the gangrenous portion of lung, together with the solidification from inflammatory exudation around this portion, furnishes dulness or flatness on percussion within a circumscribed space, which, in view of the most frequent situation of gangrene, will generally be over the scapula and below the spinous ridge. Within this space either the respiratory murmur is wanting or there is a feeble bronchial respiration, with, perhaps, either exaggerated vocal resonance or weak bronchophony. Moist bronchial or bubbling râles are likely to be heard within and around this space. If the patient survive the sloughing and removal by expectoration of the decomposed mass, the cavernous signs may be discovered. I have repeatedly found a well-marked cavernous respiration, and I have observed a circumscribed depression in front corresponding to the situation and size of the gangrenous cavity.

As regards PROGNOSIS, if circumscribed gangrene do not occur under circumstances which are dangerous, irrespective of the gangrene, recovery may take place. The chances of recovery are differently estimated by different writers, which perhaps may be accounted for by supposing that the diagnosis of gangrene is not infrequently based on insufficient grounds. It can hardly be doubted that the result is fatal in a large majority of cases. Hæmoptysis, as already stated, sometimes takes place in connection with the separation of the slough, and I have known the hemorrhage to be so abundant as to prove the immediate cause of death. Most of the cases end fatally in which the gangrene involves the pleura, perforation of the lung taking place, followed by pleuritis with pneumothorax.

The TREATMENT of pulmonary gangrene is to be directed more to the system than to the local affection. The affection never occurs under circumstances which render depletion or other debilitating measures appropriate; on the contrary, such measures can hardly fail to be pernicious. Tonic remedies and the sustaining treatment are indicated. The diet should be as nutritious as possible, and alcoholics are to be given with a freedom proportionate to the tendency to failure of the vital powers. The employment of opium in some form is important, in order to palliate pain or undue cough and to allay constitutional irritation. The chlorate of potassa has been suggested as likely to be beneficial, from its apparent usefulness in gangrenous affections of the mouth and throat. The tincture of the chloride of iron is suggested by the same analogy. Disinfectants by inhalation are indicated as long as the sputa contain decomposed matter and the breath has a fetid odor. The vapor of turpentine poured upon boiling water is a disinfectant, and has otherwise a salutary local effect. Tar vapor, produced in the same way, is useful. A solution of carbolic acid of the strength of from 2 to 4 per cent., atomized, and inhaled for a few minutes at short intervals, is probably the best disinfectant. Thymol and salicylic acid are recommended as appropriate as disinfecting inhalations.¹

[Various forms of inhalers have been devised for use in cases of fetid bronchitis and gangrene. They are made of rubber or celluloid, and are

¹ For an interesting case of pulmonary gangrene treated surgically by thoracentesis and drainage, with practical remarks, vide article by Drs. Fenger and Hollister in the *Am. Journ. of Med. Sciences*, Oct., 1881; vide, also, the *London Lancet*, May 31, 1884, for cases treated in the same manner by Mr. A. Pearce Gould.

fastened over the mouth in such a manner that the air, before being inspired, is made to pass through a wad of cotton or wool saturated with some powerful disinfectant. The drug most commonly used with the inhaler, and probably the best for this purpose, is carbolic acid of the strength of from 5 to 50 per cent. It is best to begin with the weaker solution, but if any benefit is to be derived from this method, the strength of the drug must be rapidly increased. Patients have been known to saturate the cotton of their inhalers with pure carbolic acid and to experience no evil effects from it. Creosote and turpentine may also be used to charge the inhaler.

If the gangrenous process is superficially situated and can be accurately localized by physical examination, the propriety of surgical measures should be considered. These consist in the resection of one or more ribs and the laying open of the gangrenous cavity, for which purpose the thermo-cautery may be advantageously employed. Cases have been successfully incised and drained; in fact, although recovery has by no means followed in every case, in none could death be ascribed to the operation alone.—H.]

Pulmonary Œdema.

Pulmonary œdema is always dependent on other pathological conditions, and is not entitled to be considered as an individual affection. It is, however, an event of frequent occurrence, and is important as interfering with the function of respiration, in not a few instances proving the immediate cause of death. In œdema of the lungs there is a transudation of serum into the interlobular tissue, the alveolar walls, and the air-cells.¹

Œdema may be localized around some diseased centre in the lung, as, for example, in the neighborhood of a pneumonitis, an infarction, abscess, tumor, etc. This is distinguished as *collateral œdema*. In this case it probably results from a moderate inflammatory change in the vessel-walls, by which their permeability is increased. This variety has also been called inflammatory œdema. Hypostatic œdema, following hypostatic congestion and leading to the condition of lung called splenization, has already been referred to.

These forms differ from general pulmonary œdema, which is usually understood by the term œdema of the lungs. Here a serous transudation occurs throughout both lungs, except in portions which may perhaps present a mechanical obstacle to the entrance of the serum in consequence of consolidation, as from compression, inflammatory exudation, new growths, etc. Œdematous lungs are increased in volume and weight; retract less than healthy lungs upon opening the chest; have a characteristic boggy feel compared to that of a sponge filled with water; and pit on pressure. They are less buoyant than normal lungs, but they do not sink in water. The color is usually red, but it may be pale. On section, a serous or sero-sanguinolent liquid escapes in abundance, usually mixed with air-bubbles. The same frothy liquid is present in the bronchi and usually in the trachea. [If the patient is icteric, the fluid may be of a yellow hue; and if the lungs contain much pigment, as in cases of anthracosis, it may be brown, or even black.—H.] Microscopical examination in cases of acute general pulmonary œdema shows the pulmonary capillaries widely distended with blood, and the contents of the alveoli and bronchi to consist of serum containing a considerable number of red blood-corpuscles, some granular epithelial cells washed off from the alveolar walls by the transuding serum, and free granular matter. The red

¹ Posner (*Virchow's Archiv*, Bd. 79, p. 362, 1880) finds that the dropsical effusion is first into the walls of the air-cells, and that it may be confined to them (interstitial œdema). Usually, however—and in the higher grades of œdema always—the serum escapes also into the air-cells.

which is present in the serum, have escaped by passing through the alveolar septa. It is a symptom of various pathological conditions, sometimes chronic, which it may not complicate. In some sense of which it is a necessary accompaniment of asphyxia, when it seems to be rather a symptom. Of the affections during the course of which it most frequently occurs, may be mentioned, in this disease, valvular lesions of the heart, especially of the mitral valve, cerebral lesions of the anæsthetic type, cerebral lesions of the convulsive type, and hæmiplegia giving rise to a paralysis of the respiratory muscles. It also occurs during these and other diseases, and becomes entangled. It is frequently developed in a very rapid manner, and is accompanied by a rapid increase with respiration. The great variety of its development, the inconstancy of its development under the same conditions, the rapidity of its onset in many cases, and its occurrence among the considerations which at first seem to have no analogy to the dropsical conditions of the lungs, which render difficult the explanation of

its occurrence by obstruction at the mitral orifice, and the only predisposing, not immediate, causes of its occurrence, the fact that all these conditions may exist without the development of œdema of the lungs. This fact is not explained by the establishment of these states of the heart, but by the addition of some other factor which acts as a factor which is capable of developing œdema of the lungs, which can appear suddenly and as rapidly as the dropsical effusions. But this factor must be something which acts on the pulmonary capillaries; for that œdema is not a result of increased tension in the pulmonary veins, as by mitral obstruction, but a result of increased tension in the pulmonary capillaries, as by a minority of cases of pulmonary hypertension. It is probable that the cause of œdema of the lungs must be greater, in order to produce the dropsical effusions. He, however, found that an efficient cause of œdema of the lungs is the paralysis of the left side of the heart, and that the right side of the heart is all or less impaired. Neither general nor local causes of the right ventricle suffices to produce œdema of the lungs. It is proved experimentally, it appeared that the heart is so much weakened that it could not propel the amount of blood propelled by the left ventricle, and that the blood accumulated in the lungs until the pressure was sufficient for the transudation of fluid into the alveoli. It is an assumption that disproportionate causes of acute general pulmonary œdema are the cause of its singular phenomena. Such a cause is not sufficient to develop suddenly, to rapidly develop, and to develop in cases, especially when the general condition of the lungs is "œdema," *Voelcker's Archiv f. Path.*

activity of the heart is impaired; for it is not denied that the general force of the heart is weakened in most cases of pulmonary œdema; and, indeed, it is hardly conceivable that the left ventricle should lose its wonderful power of adaptation to the obstacles which it has to overcome in propelling the blood, before the whole heart had suffered in its function. Œdema of the lungs occurs during the death-agony, when the left ventricle loses its power more rapidly than the right, or dies faster, so to speak. While the hypothesis of Welch as to the immediate cause of pulmonary œdema is not controverted by clinical facts, but, on the other hand, seems to explain them better than any other, we as yet know of no means of determining in man the relative force of the two sides of the heart, and upon the absolute strength of either right or left ventricle only subordinate weight is placed. Other influences adduced to explain the cause of œdema of the lungs are impaired nutrition of the walls of the pulmonary capillaries and vaso-motor disturbance.¹

The SYMPTOMS of œdema are increased frequency of the respirations and dyspnoea in proportion to the extent of lung affected, together with more or less cough and serous expectoration or bronchorrhœa. The displacement of air in the air-cells by liquid gives rise to dulness more or less marked on percussion over a space corresponding to the œdematous portion of lung, and within this space the respiratory murmur is weak or lost or it may be feebly bronchial or broncho-vesicular. The vocal resonance may be increased. The presence of liquid in the smaller bronchial tubes is denoted by fine mucous or subcrepitant râles. It is stated that a true crepitant râle may be produced, but this must be extremely rare. The diagnosis is to be based on dulness more or less diffused on both sides of the chest, associated with moist bronchial râles, pneumonitis being excluded, and the existence of Bright's disease, cardiac lesions, and other predisposing conditions being considered.

The TREATMENT must have reference to the circumstances under which the œdema occurs. Occurring in connection with disease of the kidneys, those measures are indicated which are applicable to dropsical effusion in other situations—namely, hydragogue cathartics and sudorifics selected and regulated according to the circumstances belonging to individual cases. When incidental to disease of the heart the main reliance is upon revulsive measures, in connection with such remedies as the condition of the heart may claim irrespective of this result. In the cases in which it is dependent on adynamia and an impaired condition of the blood, tonic and sustaining measures are called for. The liability of its occurrence in connection with hypostatic congestion in fevers and other protracted diseases, accompanied by feebleness of the circulation and depression of the vital powers, renders it an important part of the treatment of these diseases to see that the patient be not allowed to lie constantly in one position. The position of the body should be frequently changed, in order to obviate the gravitation of blood to the dependent portions of the lungs.

The name *acute* pulmonary œdema distinguishes cases in which the œdema occurs suddenly to such an extent as to give rise to great dyspnoea, sometimes quickly causing death by apnoea. In such cases prompt and efficient measures of treatment are called for. Venesection, if the action of the heart be not extremely feeble, is the most promptly efficient measure for relief, and should be resorted to at once when the symptoms denote imminent danger. Perhaps under no other circumstances is it more apparent that the physician has saved the life of a patient than in certain cases of acute pulmonary œdema in which venesection was employed. Occurring in connection with dilatation

¹ See article by H. F. Borden, M. D., *Boston Med. and Surg. Journal*, 1880.

of the heart, or when accompanied with great feebleness of the pulse and cyanosis, the application of a considerable number of dry cups to the chest may be substituted for bloodletting. To these may be added mustard to the chest and stimulating foot-baths. Ethereal and alcoholic stimulants should be given freely. I have known the inhalation of oxygen to afford marked relief.

New Growths within the Chest.

Intrathoracic tumors include nearly all the different varieties of new growths with which we are acquainted. Their consideration in detail belongs to works on pathological anatomy. Reference here will be made only to those rendered practically important by reason of their frequency or their gravity.

Pulmonary carcinoma may be primary or secondary. Primary carcinoma of the lungs is a very rare affection. As a rule, only one lung is involved, the right lung more frequently than the left. Primary cancer of the lungs may be either of the cylindrical-celled variety, in which case the tumor originates in the larger bronchi, or it may be of the flat-celled variety, in which case the tumor originates in the respiratory bronchioles or the air-cells. In the latter form of carcinoma the stroma consists of the pre-existing alveolar walls, and the appearances are sometimes not unlike a diffuse pneumonia. Primary cylindrical-celled carcinoma of the lungs usually appears as a circumscribed tumor; primary flat-celled carcinoma may be either circumscribed or infiltrated. Hemorrhages are likely to occur in primary cancers of the lungs. Sometimes softening and breaking down of the cancerous mass occurs, whence may arise cavities, abscesses, or gangrenous foci. Secondary inflammation is present in the lung-parenchyma surrounding the cancerous deposit.

[The causes of primary carcinoma of the lung, like those of cancer elsewhere, are unknown. Occupation or environment is certainly concerned in its production, as shown by the extraordinary prevalence of primary pulmonary carcinoma among the laborers in the cobalt-mines of Schneeberg. It is said that 75 per cent. of the deaths among these workmen are caused by this disease. The affection has been ascribed to the inhalation of arsenic which is combined with the cobalt.—H.]

Secondary cancer of the lungs is common. It is frequently consecutive to cancer of the stomach and to cancer of the breast, and it may be secondary to cancer in any part of the body. The relation of the lungs to the venous system of the body renders these organs the frequent seats of secondary tumors in general. Secondary pulmonary cancer is usually in the form of nodules varying in size from that of a pea to that of an orange, and disseminated throughout both lungs. Sometimes the lungs, as well as other organs of the body, are studded with small cancerous nodules (general or miliary carcinosis). Sometimes the lymphatic vessels of the pleura and of the lungs are filled with cancerous cells, in which case these vessels appear as a network of white varicose bands. The secondary deposits in the lungs usually reproduce the structure of the primary tumor.

In pulmonary carcinoma the bronchial lymphatic glands, and not infrequently the mediastinal, the cervical, and the axillary glands, are involved.

A form of cancer, which is sometimes described as *endothelioma* or endothelial cancer, occurs primarily in the pleura. The same form of tumor is also described as originating in the lymphatic vessels of the pulmonary parenchyma.

The pleura may be studded with secondary cancerous nodules without any tumors in the lungs. Cancer of the pleura is often accompanied with

abundant liquid effusion in the pleural cavity. The effusion is frequently hemorrhagic, and usually contains clumps of large epithelial cells, described as grouped cells and budding cells. The recognition of these clumps of cells in fluid withdrawn from the pleura during life may give valuable aid in diagnosis.

Of the malignant tumors within the chest, *lympho-sarcoma* is among the most important. Its origin is in the cervical, the mediastinal, or the bronchial lymphatic glands. Lympho-sarcomata grow more frequently in the anterior than in the posterior mediastinum. These tumors frequently extend into the lungs, advancing chiefly along the adventitia of the blood-vessels and of the bronchi. The tumor is composed of cells, mostly small round cells, enclosed in a network of anastomosing fibres like the framework of the lymph-glands. Caseous degeneration is rare, but a fibroid metamorphosis is more common. [In very rare instances portions of the sarcomatous growth may be expectorated. A case of this sort is recorded by Eichhorst, who states that there is but one other like it in medical literature.—H.]

Enchondroma may be a primary, but it is usually a secondary, tumor of the lung.

The SYMPTOMS of intrathoracic tumors are both general and local. In suspected carcinoma the existence of the cancerous cachexia and the presence of carcinomatous tumors in other parts of the body must be considered in arriving at a diagnosis. Lympho-sarcomata present often the history of pseudo-leucocythæmia or adenia of Trousseau. In carcinoma of the lungs some diagnostic value is to be attributed to enlargement of the supraclavicular lymphatic glands and to a muco-hemorrhagic expectoration compared in its appearance to currant jelly. These two symptoms are, however, not pathognomonic or always present in pulmonary carcinoma. The chest-wall on the affected side may bulge; sometimes, however, especially in hard cancer accompanied by extensive induration, it is contracted.

The DIAGNOSIS of new growths within the chest is to be based on the symptoms taken in connection with the signs of solidification, and sometimes the cavernous signs. The physical evidence is often not very distinctive. Pulmonary phthisis is to be excluded by a careful investigation with reference to the history as well as to the existing symptomatic phenomena. The coexistence of carcinoma in some other situation or its previous existence is to be taken into account in arriving at a diagnosis of carcinomatous intrathoracic disease.

The presence of tumors, great or small, gives rise to dulness or flatness on percussion, with either suppression of the respiratory murmur or the modifications which denote solidification. The tumors may be so situated as to give rise to symptoms and signs proceeding from pressure on important parts other than the lungs. The heart may be displaced. The calibre of the trachea or bronchi may be diminished. Aphonia or laryngeal spasm may be induced if the recurrent nerve be involved. Congestion limited to the upper extremities, head, and neck, and subcutaneous œdema, denote obstruction of the superior vena cava. Pressure on the pulmonary veins may give rise to bronchorrhagia and œdema of the lungs. Compression of the œsophagus occasions difficulty in the ingestion of food and drinks. These results of pressure on adjacent parts also belong to the history of aneurismal tumors. A tumor situated in the tract of the aorta may simulate the physical signs of aneurism. It may pulsate and give rise to a murmur. I know, from my own observations, that it may occasion a double murmur; that is, a systolic and a diastolic murmur.

The enlargement of one lung by a new growth, together with either pleural transudation or suppuration, may lead the physician to suppose that he has to deal simply with a case of pleurisy or empyema. The existence of the underlying graver affection can be determined only after removal of the liquid by aspiration. On the other hand, unilateral contraction of the chest is suggestive of fibroid phthisis.

As regards **TREATMENT** in carcinoma and other new growths, all that can be hoped for is the prolongation of life by a diet as abundant and nutritious as the digestive powers will allow, together with the best available hygienic influences and tonic remedies. Palliative treatment is to be employed in accordance with the symptomatic indications.

Hydatids—Echinococci.

Among the extremely rare affections of the pulmonary organs belong hydatid productions. These may either be developed within the lungs, or they may have been developed in the liver and have made their way through the diaphragm into the pulmonary organs in the manner in which hepatic abscesses are sometimes evacuated into the bronchial tubes, circumscribed peritonitis and pleuritis taking place and leading to adhesions which prevent the evacuation from taking place into either the peritoneal or the pleural sac.

Acephalocysts within the lungs may remain latent for a variable period; that is, giving rise to few or no pulmonary symptoms. Sooner or later, however, they excite inflammation of the surrounding parenchyma and bronchial tubes, and then occasion pain, cough, expectoration, febrile movement, etc. They may be discharged by ulceration into the bronchial tubes, leaving pulmonary cavities. The affection is likely to be mistaken for pulmonary tuberculosis. Microscopical examination of the matter expectorated may show the hooklets of echinococci or pieces of the sac with its characteristic striation and hyaline appearance. Without the demonstration of one of these the diagnosis is impracticable. The question as to the primary seat of the cysts is to be settled by the previous history, which, if they come from the liver, will show the existence of hepatic trouble prior to the occurrence of pulmonary symptoms.

The presence of hydatids in the lungs always involves great danger; and the danger is greater when they are derived from the liver than when they are developed within the lungs. There is no special plan of treatment. Palliative and sustaining measures are to be adapted to the circumstances of individual cases.

Syphilitic Disease of the Lungs.

The most common manifestation of syphilitic disease of the lungs is in the form of a new growth of connective tissue (chronic interstitial pneumonia) beginning at the root of the lung and following the course of the larger bronchi and blood-vessels. By extension of the process to the pulmonary parenchyma more or less extensive patches of indurated connective tissue are produced in the central part of the lung. In rare cases the growth of fibrous tissue is so great as to cause irregular lobulation of the lungs similar to that found in syphilitic livers.

In another form of pulmonary syphilis there is new growth of fibrous tissue around the small bronchi and the blood-vessels, producing peribronchitic and perivascular fibrous nodules studding the lung.

Syphilitic ulcers may occur in the trachea and in the bronchi. These often cicatrize, and may thus lead to serious stenosis of the trachea and of the bronchial tubes.

Gummata are found, although rarely, in the lungs, both in congenital and in acquired syphilis.

There is a peculiar form of syphilitic pneumonia, sometimes described as white hepatization, which is not uncommon in new-born children affected with syphilis. In an early stage of the affection small nodules occur in the lungs; later, a large portion or even the whole of the lungs is involved. The lesion consists in an infiltration of the alveolar walls with lymphoid cells, and an accumulation of cells, chiefly epithelial in character, in the air-cells. This white hepatization, so often found in stillborn syphilitic infants, is of more pathological than clinical interest.

Of late years many cases have been reported as examples of syphilitic phthisis. Some of these cases are instances of syphilitic fibroid induration with chronic bronchitis and bronchiectatic cavities. In most of the cases which have been described as syphilitic phthisis, and which have been examined post-mortem, the lesions are not distinguished from those of chronic pulmonary tuberculosis with caseous pneumonia, and no satisfactory proof exists of the syphilitic nature of the disease. No positive proof of the occurrence of a genuine pulmonary phthisis of syphilitic origin exists. As we now possess in the tubercle bacillus, and perhaps in the bacillus of syphilis, means of diagnosis of these morbid processes, we may hope for a solution of the question as to the occurrence of syphilitic phthisis.

The diagnosis of syphilitic disease of the lung can hardly be made with certainty. Gummata and patches of central induration may be present in the lungs without causing any symptoms. If pulmonary symptoms be present, such as cough, expectoration, dyspnoea, pain in the chest, they are not distinctive. The physical signs of consolidation or of cavity (in case of bronchiectasis) may be discovered. A probable diagnosis may be based upon the history of syphilis; the recognition of syphilitic lesions in other parts of the body, especially in the throat and in the larynx; the exclusion of tuberculous disease of the lungs, particularly by examination of the sputum; and the amelioration or cure of the symptoms by antisyphilitic treatment.

Pulmonary tuberculosis may coexist with syphilis.

CHAPTER XII.

DISEASES OF THE LARYNX AND TRACHEA.

Affections of the Larynx and Trachea.—Points relating to the Anatomy and Physiology of the Larynx, which are involved in the Consideration of Diseases in this Situation.—Acute Simple Laryngitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Subacute Laryngitis.—Chronic Laryngitis.—Laryngitis Hypoglottica.—Laryngitis with Fibrinous Exudation: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Œdema of the Glottis.—Spasm of the Glottis.—Nervous Cough.—Nervous Aphonia.—Paralysis of the Laryngeal Muscles.—Morbid Growths within the Larynx.

IMPORTANT diseases affecting the respiratory apparatus are seated in the larynx and trachea. Diseases of the larynx frequently involve the trachea, but it is rare for the latter to be affected without the former, and it

will suffice to consider tracheal affections incidentally in treating of those of the larynx.

Certain anatomical and physiological points pertaining to the larynx are to be kept in mind with a view to a clear apprehension of the diseases in this situation. The larynx is composed of a number of cartilages—namely, the cricoid, thyroid, arytenoid, and epiglottis. The epiglottis was formerly supposed to be essential as a protection against the entrance of food and drink into the laryngeal cavity during the act of deglutition; the removal of this cartilage, however, in inferior animals has shown that its loss does not occasion serious inconvenience. A hospital case in which it was completely destroyed by syphilitic ulceration, as determined by the touch and the laryngoscope, has fallen under my observation. So long as ulceration existed there was considerable difficulty arising from spasm of the glottis excited by contact with food and drink, and deglutition was performed with the least annoyance while the patient was lying on the back. But after the ulceration had healed the difficulty nearly ceased, liquids and solids being swallowed without much inconvenience. The quality of the voice underwent some change, and the patient, a young woman, stated that she had not the power of producing notes in singing as before.

The small size of the rima glottidis is an important point in connection with laryngeal diseases. In the adult male, after death, it is a triangular space an inch in length, and at the base about a quarter of an inch in width, the size being still smaller in women and children. The dimensions in life vary with the two respiratory acts. When examined in a living animal, the vocal cords are found to separate widely in inspiration and to return in expiration, forming the respiratory movements of the glottis. The respiratory movements take place from a reflex influence communicated through the recurrent nerves. These points are of interest and importance in their practical applications.

Other movements of the muscles of the larynx are produced by volition in the acts of speaking. The larynx being the seat of the voice, modifications of vocal sound constitute important symptomatic phenomena of disease. In the movements concerned in phonation the will acts through branches of the spinal accessory contained in the recurrent laryngeal nerves. The laryngeal muscles are subject to spasm and paralysis.

The solidity of the walls of the larynx is an important point in connection with certain affections. The cricoid and thyroid cartilages do not readily yield to internal pressure, and hence arises obstruction from the presence of morbid products which encroach upon the small space between the vocal cords. Another point to which reference will be made is the abundance of areolar tissue beneath the mucous membrane above the vocal cords. This tissue is more abundant in the adult than in the child—a fact which will serve to account for certain differences as regards the effects of disease during and after infantile life.

The mucous membrane of the larynx is covered, for the most part, with ciliated cylindrical epithelium. Over the upper portion of the epiglottis, the true vocal cords, and a portion of the posterior surface of the laryngeal cavity, however, the epithelium is of the pavement variety. The mucous membrane is in most places loosely attached by lax connective tissue to the subjacent muscles and cartilage, but over the true vocal cords it is firmly adherent. Hence in the latter situation submucous inflammatory and serous effusion cannot well occur. Racemose mucous glands are abundant in the larynx. None are present in the true vocal cords. The mucous membrane and the submucous tissue are rich in elastic fibres.

Of the affections of the larynx, those involving inflammation will be first

considered. Inflammation here may be simple; that is, not distinguished by any unusual features save those which are incident to the situation of the affected mucous membrane. On the other hand, it may be accompanied by fibrinous exudation. The latter will be considered under a separate head. Simple inflammation may be either acute, subacute, or chronic. These three varieties are to be considered separately. The appropriate name for inflammation affecting the larynx is *laryngitis*; this name should take the place of the terms *angina* and *cynanche*, which were formerly in vogue, but are now rarely used. The term *croup* is applied to laryngitis with fibrinous exudation, and it has also been applied to simple laryngitis and to a non-inflammatory affection—namely, spasm of the glottis—occurring in children. The first of these affections is sometimes distinguished as *true croup*, while the others are called, by way of distinction, *false croup*. The term is an unfortunate one and tends to produce confusion. I shall consider the several affections to which the term has heretofore been applied separately under their appropriate names.

Acute Simple Laryngitis.

ANATOMICAL CHARACTERS.—This variety of laryngeal inflammation is often called acute catarrhal laryngitis. During life the mucous membrane is reddened and swollen, as demonstrated by means of the laryngoscope; but after death the congestive hyperæmia is less marked, and may even entirely disappear under the pressure of the abundant elastic fibres. Small ecchymoses are not infrequently observed. The inflammatory products consist of serum and pus mingled with an abundant secretion of mucus. The first product is chiefly mucus; later, this becomes opaque from admixture with a larger number of pus-cells, and in severe cases it becomes distinctly purulent. Ciliated epithelial cells do not appear in the expectoration, and they are not usually desquamated. The mucous glands are swollen, and through their orifices often little drops of muco-pus can be pressed. The mucous membrane and submucous tissue always contain some pus-cells. The amount of swelling of the loose submucous tissue varies in different cases. In severe cases it becomes so swollen from infiltration with serum and pus as to endanger life by interference with respiration. Sometimes erosions or even superficial ulcerations of the mucous membrane are formed. They either have their origin from ecchymoses or they are follicular and seated in the mucous glands.

CLINICAL HISTORY.—The symptoms of acute laryngitis are intelligible when the morbid changes are considered in connection with the small size of the rima glottidis and the unyielding walls of the larynx. Simple swelling of the mucous membrane may produce more or less distressing symptoms and danger due to narrowing of the aperture of the glottis; but with submucous infiltration added the obstruction is increased, and may prove fatal by suffocation. The obstructive effect of the morbid changes explains the symptomatology and danger. The chief element of danger is the submucous infiltration. This occurs in varying degrees, the severity of the local symptoms and the danger being in proportion to its amount.

The development of the disease may be preceded by subacute laryngitis or a common cold. The voice is at first hoarse, and, with the development of acute inflammation, is lost. The aphonia is accompanied with a stridulous cough and a small expectoration of glairy mucus, which may be streaked with blood. Febrile movement is more or less intense or it may be wanting.

These symptoms may exist without notable difficulty of breathing, provided the changes be limited to the membrane and the swelling be not great.

With a greater amount of swelling, together with submucous infiltration, labored respiration and dyspnoea are added. The obstruction affects both inspiration and expiration, but especially the former, owing to the fact that the infiltration is greatest above the rima, where the areolar tissue is most abundant. The respiration is stridulous or noisy. The patient complains of a sense of constriction at the larynx, or feels as if the cavity were filled with a foreign substance. The latter symptom may be called *laryngeal tenesmus*. There is frequently more or less difficulty in deglutition. Liquids, by coming into contact with the inflamed epiglottis, excite cough and add to the distress. The labor of breathing and the dyspnoea are increased by the occurrence of spasm of the arytenoid muscles. The exacerbations of distress from obstruction are due chiefly to a spasmodic element. Paralysis of the abductor muscles may in some cases contribute to the obstruction. The obstruction will then be manifested more in the act of inspiration than in expiration.

In cases of acute laryngitis with great obstruction the suffering is intense. The face and eyes are swollen and congested, the countenance denotes anguish, and after a time lividity occurs. The distress is much increased during the exacerbations caused by spasm, and in the intervals of comparative ease the patient manifests drowsiness, but is unable to obtain refreshing sleep. With the muscular efforts to enlarge the aperture of the glottis, the larynx rises and falls in the acts of inspiration and expiration. There are frequent efforts to cough and expectorate, as if to get rid of an accumulation within the larynx. The cough may be dry and croup-like, but is oftener husky or abortive. The larynx is sensitive to pressure. Pitting over the pomum Adami has been observed. The respiratory acts are less frequent than in health. In a case which I have recorded they were 12 per minute.

With these symptoms in a large proportion of cases the disease ends fatally if tracheotomy be not resorted to. The mode of dying is by apnoea, and it may take place either gradually or suddenly in an exacerbation of unusual violence.

Assuming that other affections do not coexist, the symptoms, in addition to those which relate directly to the laryngeal obstruction, are incidental to fever—deficient oxygenation and decarbonization of the blood, together with the suffering which belongs to the disease. Slight delirium may occur toward the close of the disease if it be prolonged, but in general the mental faculties are unaffected.

PATHOLOGICAL CHARACTER.—In simple acute laryngitis the inflammation has no special characteristics. The severity and danger are not owing to the intensity or extent of the inflammation. The same amount of inflammation in other situations would constitute a trivial affection. The gravity is due to the fact that the usual results of inflammation in this situation obstruct the passage of air through the larynx, in consequence of the small size of the rima glottidis and the unyielding laryngeal walls. In children simple acute laryngitis gives rise to croupy cough and respiration, and hence this is one of the different affections formerly embraced under the name croup.

CAUSATION.—Acute laryngitis, with the symptoms stated in the Clinical History, in the adult is extremely rare.¹ It is less rare in infants and children

¹ Some writers reckon as cases of acute laryngitis those in which the symptoms denote a less dangerous form of the disease than the one here considered under this heading. Of course the disease is less rare if the term acute be extended to cases of moderate severity.

than after adult age. Its infrequency is remarkable in view of the frequent occurrence of inflammation in the pharynx; and the fact exemplifies the principle of conservatism involved in the law by which inflammation does not tend to extend from one part to other parts, although in immediate proximity. I have seen a case in which the pharynx was laid open by a gunshot wound in the neck, so that the top of the larynx could be seen through the wound, and yet during the progress of recovery there was no evidence of the slightest laryngeal inflammation.

Occasionally, however, laryngitis is developed in connection with pharyngitis. This was observed in some cases of the so-called epidemic erysipelas, or "black tongue," which formerly prevailed in many parts of this country. I have known it to occur in connection with the pharyngeal affection in scarlatina. The laryngitis which, in a subacute form, is common in rubeola sometimes becomes acute. Acute inflammation may be excited in variola by the occurrence of the eruption in this situation. Under the several circumstances just named it is a secondary affection. It may occur as a primary affection after exposure to cold and wet, as in the case of Washington.

It might be conjectured that excessive use of the voice would be likely to predispose to this affection, but clinical observation furnishes little proof that such is the fact. It may be produced traumatically by the inhalation of irritating vapors. Many cases have been reported in which young children have produced the disease by sucking boiling liquid and steam from the spout of a water- or tea-pot.

DIAGNOSIS.—The diagnostic characters of acute laryngeal inflammation are the loss of voice, and the husky, stridulous cough, in connection with the fever and other symptoms. That the labor of breathing and the dyspnoea are due to the obstruction of the larynx is shown by the sensations of the patient, the diminished frequency of the respiratory acts, and the absence of physical signs denoting pulmonary disease. In proportion as the aperture of the glottis is narrowed the respiratory murmur will be weakened, and this affords a better criterion of the amount of obstruction than the sufferings of the patient. The only difficulties in diagnosis relate to the discrimination of simple acute laryngitis from laryngitis with fibrinous exudation, from oedema of the glottis, and from spasm of the laryngeal muscles. In arriving at the conclusion that simple acute laryngitis exists, the affections just named are excluded by the absence of distinctive circumstances belonging to the clinical history of each. Suffice it to say here that the presence or absence of fibrinous exudation in cases of laryngitis is generally determinable; that oedema of the glottis may be ascertained; and that spasm without inflammation or with only subacute inflammation is wanting in characters which are essential to the diagnosis of acute laryngitis. If a satisfactory laryngoscopic examination can be made, the diagnosis is demonstratively established.

PROGNOSIS.—Acute laryngitis in the adult is a grave affection. The gravity, as already stated, depends in a great measure on the submucous infiltration. Cases without this contingency occur, and may end favorably without very alarming symptoms. The suffering in these cases arises measurably from spasm. If the constant obstruction—*i. e.* obstruction exclusive of that due to spasm—be sufficient to interfere greatly with respiration, the tendency is to a fatal result. A proportion of such cases will end fatally if life be not saved by timely surgical interference. The course of the disease in fatal cases is rapid. It has been known to prove fatal in seven hours. The duration rarely exceeds a week.

In young subjects this disease is less severe and less likely to prove fatal

than in adults, notwithstanding the smaller size of the rima glottidis in early life, the difference being probably due to the fact that submucous transudation is less in children.

TREATMENT.—The treatment of acute laryngitis embraces general and local measures. The general measures are those designed to lessen the intensity of inflammation and to promote resolution and the absorption of serous transudation. The employment of bloodletting is to be guided by the same principles as in other inflammations, but the evils and danger of abstracting blood are not so great as in certain other inflammations—for example, lobar pneumonia—because there is not the amount of morbid effects to be recovered from, and it is therefore not so important to spare the vital powers for the processes of restoration. The danger in acute laryngitis, it is to be borne in mind, is not from the extent or degree of the inflammation or from the lesions which it may induce *per se*, but it is incidental to the seat of the inflammation. And if a fatal result take place, the dying is by apnoea, not by asthenia. But in the use of bloodletting and other depressing measures this consideration must be kept in view: the patient's strength is not to be so far diminished as to incapacitate for the prolonged muscular exertions which the labor of breathing may require. Bloodletting should never be practised after the occurrence of lividity of the prolabia and face. Under these circumstances a fatal result would be hastened by abstracting blood.

The bowels should be moved efficiently by cathartics of the saline class. Nauseant or the direct cardiac sedatives are indicated as in other inflammations. Nauseant remedies should not be carried so far as to produce vomiting, which will add greatly to the distress and tend to aggravate the inflammation. If antimony be used, it should be given largely diluted, to avoid its local action on the throat.

Mercurialization may be advocated in this as in some other affections on the following ground: Although the antiphlogistic and sorbefacient power of mercury have doubtless been heretofore greatly overestimated, it is by no means certain that it exerts no remedial influence in these directions. So long, therefore, as there is room to suppose that it may be useful in any degree, it should be employed in an affection like this, which frequently tends rapidly to destroy life by apnoea. The general depressing effect and other evils of mercurialization are of little moment, provided the remedy prove in any degree useful in its influence on the local affection. If mercurialization be determined on, it should be induced early and rapidly, either by large doses guarded with opium or by small doses repeated at short intervals, mercurial inunction being added.

Remedies to allay spasm and cough are indicated. The spasmodic element may be more or less prominent. Its degree of prominence is shown by the frequency and severity of the paroxysmal distress, whereas the amount of obstruction due to the swelling and infiltration is shown by the labor of breathing in the intervals between the paroxysms or exacerbations. Opium and antispasmodic remedies are important in proportion to the amount of suffering from spasm, but opiates should not be carried so far as to blunt the perception of the want of breath. If belladonna be found to meet the indication, it is to be preferred to opiates.

In the foregoing remarks on the general measures of treatment reference has been had especially to idiopathic or primary laryngitis. When the affection occurs as a complication of scarlatina, rubeola, or variola, and if it be associated with pulmonary or any other important disease, the same measures may not be admissible. This statement applies to bloodletting, mercurialization, and other depressing measures. Inflammation of the trachea fre-

quently, if not generally, coexists, and bronchitis may be developed in accordance with the law respecting the extension of inflammation in the air-passages—namely, that it tends to travel downward and but rarely upward. Of course the general symptoms, febrile movement, etc. will be increased in proportion to the extent of mucous surface inflamed.

The local measures of treatment embrace fomentations or poultices applied to the neck, with a blister, perhaps, applied over the sternum; and the atmosphere of the apartment should be charged with steam or the vapor of hot water should be inhaled by means of a convenient apparatus. The former is vastly more effective, and is therefore to be preferred. The application to the throat of compresses dipped in ice-water and renewed at intervals of a few minutes is a measure which may be tried with safety, and if it afford relief it may be often repeated, being continued as long as it is a source of comfort to the patient. Early in the disease it may act favorably as an antiphlogistic, and afterward it may afford relief by diminishing spasm. According to Cohen, it is indicated when the obstruction is caused in a measure by paralysis of the abductors.

When the membrane, on laryngoscopic examination, shows much tumefaction above the vocal cords, Cohen advises scarification of the parts. If this measure be not practicable or if it prove ineffectual, tracheotomy is to be employed, provided the obstruction become so great as to render danger of death imminent. Patients should never be allowed to die from strangulation for want of timely surgical interference. If the danger be purely or chiefly from apnoea, this operation will prove the means of saving life. The important question is, When is it to be performed? It should not be delayed until permanent lividity occurs; that is, lividity due to the obstruction caused by swelling and infiltration irrespective of spasm. Persisting lividity denotes imminent danger, and impairs the probability of success from the operation. It is advisable not to delay either scarification or tracheotomy, or both, until lividity occurs, but to resort to surgical interference whenever the obstruction is sufficient to occasion sinking in of the soft parts and retraction of the lower part of the chest in inspiration.

After convalescence is established the recovery of the voice is slow, the pitch and quality remaining altered for some time.

The treatment of acute laryngitis in children, owing to its being a less severe and grave affection than in the adult, claims less vigorous treatment. Cases frequently, if not generally, do well with simple palliative measures. Emetics may be important in order to effect the removal of viscid mucus from the larynx. Death may be produced solely by obstruction due to the accumulation of mucus in this situation. It will hardly be supposed that the larynx may be so tolerant of obstruction from this source that, occurring in a healthy child, efficient efforts of coughing would not be excited and life be destroyed by slow apnoea; yet a case exemplifying the fact has fallen under my observation.

Subacute Laryngitis.

Subacute inflammation of the larynx is of frequent occurrence, either as preceding the development of bronchitis, or the inflammation not extending to the bronchial tubes. It characterizes certain cases of the affection commonly known as "a cold." The inflammation is of a low grade of intensity, and is not accompanied by submucous effusion. There is either hoarseness or aphonia, with cough and an expectoration at first transparent and viscid, and afterward opaque, thick, and loose. There is no obstruction to respira-

tion. Laryngeal spasm in the adult is rarely excited. There is little or no fever.

It is important only as involving some liability to an increase in the intensity of the inflammation or the development of the acute affection; but the liability to this is small. The measures of treatment are those indicated in cases of bronchitis or a "cold."

Subacute laryngitis exists in a certain proportion of the cases formerly included under the name croup. The croup phenomena are due to spasm of the laryngitis being an unimportant element. This variety of so-called croup is unattended with danger, however violent may be the symptoms referable to spasm.

Chronic Laryngitis—Laryngeal Ulcers.

Chronic laryngitis occurs much more frequently than the acute form; it occurs, therefore, often without having been preceded by acute laryngitis. Acute laryngitis, in fact, if it do not destroy life, ends in recovery without eventuating in the chronic affection, and, on the other hand, in chronic laryngitis the inflammation rarely becomes acute.

In chronic inflammation the hyperæmia is less intense than in acute laryngitis. The mucous membrane has a grayish color, and often presents to view dilated veins. A mucous or purulent secretion coats its surface, which is often granular from enlargement of the mucous glands. The vocal cords lose their smooth, glistening appearance, and are grayish or opaque. The flat epithelium covering them becomes thickened, and often in other portions of the larynx the normal cylindrical epithelium is replaced by the pavement variety. By development of new connective tissue the mucous membrane and submucous tissue often become thickened, and occasionally papillomatous growths project into the cavity of the larynx. Instead of being hypertrophied, the mucous membrane in some cases is atrophied. Ulcerations more or less deep and extensive are frequent in chronic laryngitis due to specific causes.

In the majority of cases chronic inflammation in this situation occurs in connection with either syphilis or pulmonary phthisis. The localization of syphilis in this part is rare, so that the existence of chronic laryngitis constitutes presumptive evidence of the existence of phthisis. In cases of pulmonary phthisis with chronic laryngitis it was formerly supposed that the latter precedes the former, and that the disease extends from the larynx to the lungs. The term *laryngeal phthisis* was used to distinguish the affection in these cases. Improvement in the means of detecting a tuberculous deposit in the lungs, however, has led to a knowledge of the fact that the laryngitis in nearly all these cases is secondary, the pulmonary disease being first developed. The laryngeal ulcers which complicate pulmonary phthisis are most frequently seated on the posterior surface of the larynx, just above the commissure of the vocal cords. In many cases a single small ulcer in this situation is found. This may, however, extend in depth and surface, and others may likewise appear. The vocal cords may be nearly destroyed by phthisical ulceration, and one or more small ulcers are often found on the epiglottis. The smaller ulcers are usually round, and the larger ones have festooned borders. The edges are thickened. The ulcers appear to be always due to the breaking down of tuberculous products. Tubercle bacilli are found in the walls of the ulcer and in the secretion from its surface.

While phthisical ulcerations most frequently begin just above the vocal cords, syphilitic affections are usually first developed in the upper portion of the larynx. *Syphilitic laryngitis* in general follows syphilitic disease of the pharynx and base of the tongue. In the later stages of syphilis laryngeal

ulcerations, often of the most destructive character if not properly treated, may be developed. These usually begin on the epiglottis and extend downward. They may attack the vocal cords, and even extend into the trachea. They are accompanied usually with much induration and thickening of the submucous tissues. When the ulcers heal, sometimes deforming cicatrices are formed, which may lead, especially on or about the vocal cords, to dangerous and even fatal stenosis.

Inflammation of the tissues immediately surrounding the laryngeal cartilages is called *laryngeal perichondritis*. Suppurative perichondritis is most frequently the result of syphilitic or phthisical ulcers in the larynx. It occurs as a very rare complication in infectious diseases of an asthenic type. The non-vascular cartilage suffers in its nutrition, and often becomes partly or wholly necrotic, so that loose pieces of cartilage, usually calcified or ossified, are found bathed in pus. If the collection of pus open into the laryngeal cavity, the dead pieces of cartilage may be coughed out. A necrosed fragment of cartilage has been known to become lodged in the glottis and to cause death by suffocation. Sometimes the perichondrial abscess opens externally, and through the opening necrosed cartilage may be discharged.

The most characteristic of the SYMPTOMS of chronic laryngitis relate to the voice. It becomes either hoarse, husky, or stridulous, and it may be lost; that is, there is either difficulty of speech (dysphonia) or its extinction (aphonia). If aphonia exist, the patient speaks in a husky whisper. The extent to which the voice is affected is not a criterion of the extent to which the vocal organs are damaged by ulceration. Slight ulcerations and thickening may lead to great huskiness, and even extinction of the voice. If notable hoarseness exist, more or less destruction of the vocal cords, enlarging the rima glottidis, may be suspected.

As regards cough, its prominence as a symptom varies in different cases. It is modified like the voice; that is, it is either hoarse, husky, or stridulous. The expectoration also varies. It may be slight or more or less abundant. Its characters may be those of mucus, muco-purulent matter, or pus. Not infrequently it presents bloody streaks, and it may be fetid. The bloody streaks and pus point to ulceration; the fetor points to caries of the cartilages. Cough and expectoration, however, it is to be borne in mind, are measurably due to the tuberculous affection of the lungs with which the laryngitis is generally associated. Some cases of tuberculous laryngitis are characterized by violent paroxysms of cough resembling those of whooping cough, and vomiting may occur during the paroxysms.

A marked difference in different cases relates to deglutition. In some cases the act of swallowing is attended with no inconvenience, but in a certain proportion of cases it is a source of great distress. The passage of food and drink causes pain, excites spasms of the glottis, thus occasioning distressing dyspnoea, and frequently liquids are returned through the nostrils. Patients are obliged to confine themselves to the blandest articles of diet, and even these are sometimes ingested with so much difficulty that death is hastened by inanition. The difference in different cases depends on the situation of the ulcerations, these extending sometimes above the vocal cords and upon the epiglottis, where the ulcerated surface comes in contact with the food and drink in the act of swallowing, and sometimes being sufficiently below the top of the larynx to be secure from this source of irritation.

The DIAGNOSIS of chronic laryngitis is easy; the morbid characters of the voice at once indicate the affection. Its connection with pulmonary phthisis is to be determined by a physical exploration of the chest and examination

of the sputa, together with an examination into the previous history and symptoms. If pulmonary disease be excluded, the syphilitic source of the affection is to be investigated. The affection may be regarded as idiopathic in cases in which both syphilis and phthisis can be excluded; but, as already stated, such cases are rare.

The PROGNOSIS in cases of chronic laryngitis will of course have reference to its pathological associations. Its connection with phthisis does not render the latter disease more rapidly progressive; on the contrary, the progress of the tuberculous affection of the lungs is, as a rule, more slow with than without this complication, provided it do not interfere with alimentation. Thus associated, however, the laryngitis is rarely recovered from. The inflammation and ulcerations usually continue, but if not, the voice remains permanently more or less impaired. Considerable improvement may take place in cases of tuberculous laryngitis, although the affection continue. Chronic laryngitis dependent on syphilis offers a better prospect of recovery. The voice, however, after recovery will be very likely to remain permanently affected.

In my experience cases of tuberculous laryngitis have not presented notable embarrassment of breathing from obstruction. In not a few of the cases, however, of syphilitic laryngitis which I have seen there has been sufficient stenosis to render respiration more or less labored, and in some cases obstruction threatened life by apnoea. In a number of cases which have come under my observation at Bellevue Hospital the operation of tracheotomy has been resorted to, and, apparently, the lives of patients thereby saved. It has sometimes been resorted to more than once in the same case.

[A dangerous result of chronic laryngitis, from whatever cause, is hypertrophy of the inferior vocal cords, which hypertrophy may be so great as to cause these processes to project like a diaphragm into the calibre of the larynx and give rise to the most alarming dyspnoea. In such cases tracheotomy must be promptly resorted to.—H.]

The TREATMENT of chronic laryngitis, as regards general measures, will have reference to its pathological relations. In the great majority of cases the treatment must be that indicated by the coexistence of pulmonary phthisis. If the affection be traceable to syphilis, the antisyphilitic remedies are called for—namely, mercury and the iodide of potassium.

As regards local measures, counter-irritation over the neck by means of the croton oil or small blisters is sometimes useful, even in cases of phthisis. The local treatment, however, relates especially to applications to the affected part: that is, within the larynx. The injection of medicated liquids and the insufflation of remedies in the form of a dry powder are objectionable, owing to the difficulty of limiting the application to the diseased parts and to the cough and spasm which they are liable to excite. A more satisfactory method is the introduction of a sponge attached to a probang properly curved. Owing to the enlargement of the glottis which takes place in the act of inspiration, the introduction must be made during the act of inspiration. During the act, as is well known, foreign bodies of large size are sometimes drawn with the inspired breath into the air-passages. The nature and seat of lesions within the larynx may be ascertained by means of the laryngoscope, and the knowledge thus obtained affords aid in judging as to the propriety of topical applications and in showing the particular points at which they are to be made.

The topical remedy most frequently applied by means of the sponge is the nitrate of silver. A strong solution is commonly used—namely, from one to

two scruples to the ounce of distilled water. The sponge, moistened by this solution, is carried between and below the vocal cords. Spasm of the glottis occurs, and the liquid, being expressed from the sponge, comes into contact with the whole of the interior surface of the larynx. This application is sometimes beneficial, affording immediate and marked relief. It may then be repeated from time to time. In many cases, however, no relief is afforded, and in these cases after a fair trial it is useless to persevere in it. In the cases in which the laryngitis interferes with deglutition, relief may sometimes be afforded by narcotics and probably by codeia. The topical application of the hydrochlorate of cocaine has recently been found serviceable. [The effect of this drug is but transient, and therefore it should be employed at such times as to be of most benefit to the patient. These are the periods immediately preceding the principal meals. By the use of cocaine the painful deglutition which is so distressing to the patient may be to a great extent relieved.]

The curative treatment of laryngeal phthisis is purely surgical, and involves the use of the curette and the direct application of lactic acid, creosote, nitrate of silver, etc. The manipulations demanded by such treatment are of the most delicate description, and should be attempted by none but an expert.—H.]

Tracheotomy is to be resorted to in cases of syphilitic laryngitis whenever obstruction endangers life. The propriety of this operation as a means of promoting recovery has been advocated. For this purpose the opening is to be maintained for an indefinite period. The advantage consists in the arrest of the respiratory movements of the laryngeal muscles, which is a result of breathing through the trachea.¹ This measure has also been advocated in cases of laryngitis associated with pulmonary phthisis, the objects being complete rest of the larynx and the prevention of the passage of the matter of expectoration over the ulcerated surfaces. It has proved a useful measure in some reported cases.² An objection to it in cases of phthisis is the obstacle which a tube in the trachea offers to free expectoration. If found to be useful, its usefulness will probably be limited to the cases in which the laryngeal affection involves dysphagia and in this way interferes with alimentation.

Inflammations may occur in that part of the larynx situated below the vocal cords. Inflammation in this situation is called *laryngitis hypoglottica*. The inflammation may be confined to this region. Acute subglottic laryngitis is often attended by great swelling of the submucous tissue in consequence of infiltration with serum and pus-cells. The affection is a grave one on account of the obstruction to respiration. Usually, both acts of respiration are difficult. The diagnosis is readily made by means of the laryngoscope, which reveals the situation of the swelling to be just below the true vocal cords. Tracheotomy is frequently indicated by the severity of the symptoms.

Chronic inflammation of the mucous and submucous tissues of this part of the larynx is characterized by a new growth of connective tissue (*laryngitis hypoglottica hypertrophica*). The affection is rare and of a peculiar nature, being in some cases apparently dependent upon the disease called rhinocleroma.

Laryngitis with Fibrinous Exudation (Membranous Croup).

It is important to distinguish between the anatomical signification and the clinical application of the names croup and diphtheria. In croup we

¹Vide article by Thomas Bryant, in the *Trans. Clin. Soc. of London*, vol. i., 1868.

²Vide article by Dr. Beverley Robinson, *Am. Journ. of Med. Sciences*, April, 1879.

may have diphtheritic as well as croupous inflammation, the difference depending chiefly upon the seat of inflammation. Decided as are the differences between membranous or true croup and diphtheria as to etiology and clinical history, essential points of difference in respect to their pathological anatomy have not as yet been established. In both diseases there is a fibrinous exudation. In croup the larynx is the principal seat of inflammation, in diphtheria the pharynx and sometimes the nares; but croup is usually accompanied with fibrinous exudation in the pharynx, and diphtheria frequently with pseudo-membranous laryngitis. In both diseases the fibrinous exudation, when seated in the trachea or in the lower portion of the larynx, is usually of the so-called croupous variety, and when seated in the pharynx or fauces, of the diphtheritic or of the pseudo-membranous variety. By so-called true or membranous croup, however, is understood a local disease characterized by fibrinous inflammation of the larynx and the air-passages; by the name diphtheria, an infectious disease with, in some cases, a similar localization of the fibrinous exudation. In this article the term diphtheria is had only to the affection heretofore known as true croup. Diphtheria is more appropriately considered under general diseases than under diseases affecting the respiratory system.

The term croup is of Scotch origin, and signifies strangulation. It has been used in a comprehensive sense to signify a variety of affections of the larynx characterized by a peculiar shrill, barking cough called the croup cough, and by difficulty in breathing. These symptoms may accompany in children simple acute or subacute laryngitis, and also spasm of the larynx without laryngeal inflammation. To such cases the name *false croup* has been applied in distinction from *true croup*, the latter term being confined only for the pseudo-membranous variety of inflammation.

The extent of the fibrinous exudation varies in different cases. In the form of a false membrane, it is found in the larynx and in the trachea. It is also present, as a rule, in the pharynx, on the tonsils, soft palate, and epiglottis. The larger bronchi are often involved, and in some instances those of small size. The larynx may be primarily affected, or the false membrane may appear first in either the pharynx or the trachea. The false membranes are whitish or grayish, or brownish-red from admixture of blood. They vary greatly in extent, thickness, and consistence. In the pharynx the mucous membrane of the pharynx or fauces the fibrinous exudation is usually in patches. In the larynx the favorite seat of the exudation is the vocal cords, which are often uniformly coated, and sometimes so thick that the glottis is nearly occluded. The false membrane may be expected to take the form of shreds or of tubular casts of the larger bronchi, or of solid cylinders from the small bronchi. The membrane, when removed, is tolerably firm consistence; it may be found on autopsy, however, as a pulpy, yellowish mass coating the mucous membrane. In the trachea and in the bronchi it can, as a rule, be readily stripped off from the subjacent mucous membrane; in the larynx it can also often be removed without tearing the mucous membrane; but it is usually closely adherent on the epiglottis and true vocal cords; in the pharynx and on the soft palate also it is intimately connected with the mucous membrane. In the bronchi, trachea, and lower portion of the larynx the fibrinous exudation is of the so-called croupous variety. In this variety, the false membrane consists chiefly of fibrillated fibrin holding in its meshes pus-cells, red blood-corpuscles, and sometimes epithelial cells. It is deposited directly upon the basement-membrane in most places, the epithelium being absent; the mucous membrane itself is swollen, hyperæmic, and contains a variable number of emigrated white blood-corpuscles, and sometimes eosinophiles, but no fibrinous exudation. On the epiglottis and in the other

of the throat the exudation is often of the pseudo-diphtheritic variety—that is, the false membrane cannot be detached without loss of substance from the subjacent mucous membrane—but there is no fibrinous material in the mucous membrane itself. The exudation, however, may be diphtheritic; that is, the fibrinous substance is present not only upon the surface, but also in the tissues of the mucous membrane. The fibrinous material in the diphtheritic and pseudo-diphtheritic forms of inflammation consists in part of fibrillated fibrin and in part of epithelial, pus-, and connective-tissue cells which have undergone the peculiar metamorphosis called coagulation necrosis. During the course of the disease the pseudo-membranes may be repeatedly exfoliated and new ones formed in their place.

Both rod-shaped and spherical bacteria are found in the false membranes, but it is not proven that they are concerned in the causation of the disease.

The lungs after death from fibrinous laryngitis often present spots of atelectasis, also an emphysematous condition, especially of the upper lobes, hyperæmia, and sometimes lobular pneumonitis, rarely the lobar form.

CLINICAL HISTORY.—The symptomatic phenomena in this variety of inflammation at the outset are the same as in simple laryngitis. The local and general symptoms may not be as marked as in cases of simple acute laryngitis. The disease is often supposed to be nothing more than a common cold. There is more or less cough, and the cough is hoarse or barking. Hoarseness or huskiness of the voice exists, and moderate fever. The symptoms denoting gravity of disease arise from obstruction due to the exudation, in connection with swelling of the glottis and the occurrence of either spasm or paralysis of the laryngeal muscles. One, two, or three days may elapse before the disturbance of respiration is sufficient to create any apprehension. Not infrequently the general symptoms do not prevent the child from being up and engaging in play even after a certain amount of obstruction has taken place. The obstruction due to the exudation and swelling is shown by labored breathing in both acts and by dilatation of the nostrils. These evidences may be apparent before the obstruction is sufficient to occasion suffering from dyspnoea. The additional obstruction due to laryngeal spasm is shown by the dyspnoea, which occurs in paroxysms or exacerbations. Spasm may be more or less prominent as an element of this form of disease; but, as a rule, it is far less prominent than in the affections heretofore known as false croup. Hence, of all the varieties of so-called croup, this, in its development and early progress, is the one least likely to excite alarm.

As the disease advances the obstruction is increased. The labor of breathing becomes greater, and is attended with manifestations of distressing dyspnoea. The current of inspired air is insufficient for the free expansion of the lungs, as denoted by contraction of the lower part of the chest, together with sinking in of the soft parts above the clavicles and sternum in the act of inspiration. The cough becomes stridulous and abortive. The voice or cry is reduced to a husky whisper. The face is congested, and an expression of anxiety and distress is marked. More or less fever continues. The sufferings are increased at variable intervals in proportion as the spasmodic element is prominent. If life be prolonged, the cough at length becomes loose, and portions of the false membrane are expectorated from time to time. The obstruction may then gradually decrease and recovery take place. If the disease prove fatal, the mode of dying is by slow apnoea; but not infrequently the suffering from dyspnoea diminishes toward the close of life, and the labor of breathing may be so far lessened as to excite delusive hopes of improvement. Convulsions occasionally occur toward the close of life.

A cause of obstruction in certain cases is paralysis of the posterior crico-

arytenoid muscles. As a result of paralysis of these muscles, dilatation of the glottis does not take place in inspiration, and obstruction during the inspiratory act occurs as after section of the recurrent laryngeal nerve. Immobility of the glottis is observed by laryngoscopic examination. In far as the obstruction is due to this cause, it will be manifested in the inspiratory act. This act may be accompanied by a laryngeal sound suggestive of a sucking inward of the glottis. Another important incidental circumstance increases the interference with respiration—namely, the accumulation of mucus in the trachea and bronchial tubes, the presence of the false membrane in the larynx, and the feeble expiratory efforts preventing expectoration. The danger from accumulation below the larynx is of course incidental to the cases in which bronchitis coexists.

[**PATHOLOGICAL CHARACTER.**—Undoubtedly, the majority of cases of pseudo-membranous laryngitis are neither more nor less than laryngeal diphtheria, but in the opinion of the writer it is going too far to deny, as some pathologists do, that there is such a disease as non-diphtheritic membranous laryngitis. The independent existence of this disease is proved by evidence both pathological and clinical. In the first place, an inflammation of the larynx attended with the exudation of fibrin may be the result of thermal, chemical, and mechanical irritants. For example, such inflammation has been frequently observed in children who have inhaled steam from the spout of a kettle. It has also been caused by the action of caustic substances, such as ammonia, caustic potash, and the mineral acids; and, finally, it has been observed in cases of foreign bodies in the air-passages. In such cases it is manifest that the diphtheritic poison has nothing to do with the production of the false membrane.

A powerful clinical argument in support of the separate individuality of "croup" and diphtheria is afforded by the statistics of tracheotomy, which are much more favorable in the former. For example, Henoch of Berlin performed tracheotomy¹ in 70 cases of diphtheria of pharynx and larynx with but 9 recoveries—i. e. 13 per cent., whereas in 36 cases of "idiopathic croup" he had 24 recoveries—i. e. 60 per cent. F. Goldschmidt² corroborates Henoch's statement that the percentage of recoveries after tracheotomy is greater in cases of so-called idiopathic croup than in those of diphtheria. For example, in the children's hospital at Nürnberg the statistics of tracheotomy were unusually favorable during 1887 (in 39 operations there were 15 recoveries—i. e. 38.5 per cent.), and during that year there were among the cases operated on an unusual number that might be fairly regarded as idiopathic croup.

As above stated, Henoch's recoveries after tracheotomy in undoubted cases of diphtheria amounted to only 13 per cent. This is much below the published results of other operators, who claim a success of from 25 to 40 per cent., and according to Henoch this apparent superiority is due to a failure to recognize the distinction between croup and diphtheria. The result of a Henoch's tracheotomies upon diphtheria and croup combined is a recovery of from 25 to 30 per cent.

These facts are certainly most significant. The defenders of the theory that croup and diphtheria are identical attempt to refute them by the statement that the cases of so-called croup are in reality cases of mild diphtheritic infection with localization of membrane in the larynx alone, but the clinical history of the two diseases differs quite as much as the results of tracheotomy just mentioned.—H.]

² *Centralblatt für klin. Med.*, No. 48, 1889.

CAUSATION.—This form of disease is generally met with in young children, but rarely in infantile life. The age in the great majority of cases is between two and seven years. The disease, however, may occur at any period from birth to the age of two years, and at any period after seven years. Boys are oftener affected than girls. It occurs oftener in some situations than in others; a cold, humid, changeable climate apparently contributes to its occurrence. Cases occur oftener in the spring and autumnal months than at other portions of the year, [and the disease often appears to take its origin from exposure to cold and wet. A negative etiological feature, but one of great importance with reference to the nature of the affection, is that it is not, like diphtheria, traceable to contagion.—H.]

DIAGNOSIS.—Considering the great fatality of this disease, the diagnosis is of great importance with reference to the prognosis and treatment. It is to be discriminated from acute simple laryngitis, from subacute laryngitis with spasm, and from a purely spasmodic laryngeal affection which is presently to be considered. In each of these affections laryngeal spasm is more or less involved, and the character of cough and respiration distinguished as croupal is chiefly attributable to that element. The spasmodic element is more likely to be prominent, especially at the outset, in the other affections just named than in this affection; in other words, in this, the so-called true croup, the croupal phenomena are less marked than in either of the forms of the so-called false croup. The insidious development of this disease, which alone of the affections formerly embraced under the name croup is attended with danger, renders it liable to be overlooked until the disease has progressed so far as to give rise to serious obstruction.

As contrasted with the other affections just named, the slow, insidious development is one of the points involved in the differential diagnosis. In the so-called catarrhal and the spasmodic variety of croup the croupal phenomena occur suddenly and violently, the attack almost always being in the night. When such an attack occurs without having been preceded by cough, febrile movement, and alteration of the voice, it is almost certain that the affection is not true croup. Alteration of the voice is an important diagnostic feature. This will distinguish membranous croup from a purely spasmodic affection, but not from simple laryngitis, either acute or chronic; the voice, however, is affected in a more marked degree in laryngitis with fibrinous exudation.

The presence of fibrinous exudation about the epiglottis, and more or less within the pharynx, is a point of great importance in the differential diagnosis. With reference to this point the observations of Ware are valuable. In his analysis of cases of the several varieties of croup, out of 33 cases of true croup—i. e. laryngitis with exudation—a pharyngeal exudation was observed in all save a single case. On the other hand, of 45 cases of the affections included under the head of false croup, an exudation within the pharynx was sought for and found to be wanting in every case. Of 19 cases observed by Meigs with respect to this point, in all but 3 an exudation occurred in the pharynx either before or after the development of the laryngitis. In view of these facts, the presence of an exudation within the pharynx, taken in connection with the symptoms which denote laryngitis, renders it extremely probable that exudation exists within the larynx. It is to be borne in mind, however, that the pharyngeal exudation is sometimes wanting, and that its absence in the larynx cannot be inferred from its non-existence in the pharynx with as much positiveness as its presence in the larynx is to be inferred from its existence in the pharynx.

In order to render the diagnosis positive, if the co-operation of the patient

can be obtained, the laryngoscope should be employed. The existence of the disease is of course demonstrated if the intralaryngeal space can be inspected.

In the progress of the disease, if it do not destroy life, the discovery of patches of false membrane in the matters expectorated should be considered as the only reliable test of the correctness of the diagnosis. The non-observance of this test has led not infrequently to cases of simple laryngitis being regarded as cases of laryngitis with fibrinous exudation successfully treated.

With capillary bronchitis this affection need never be confounded. In capillary bronchitis the respirations are frequent, panting, and gasping; in laryngitis with exudation the acts are labored and difficult, and, as a rule, not notably frequent. The embarrassed, noisy breathing, especially during sleep, in cases of enlargement of the tonsils may at first suggest the affection under consideration, but it is readily excluded by the absence of the croupal cough and of hoarseness. Retro-pharyngeal abscess is to be excluded.

[It must be acknowledged, in spite of what has been said concerning the pathological character of this disease, that it is very difficult to draw a clear line of demarcation between membranous laryngitis and laryngeal diphtheria. In the opinion of the writer, a diagnosis of the former is justified when, with hoarseness, cough, partial or complete aphonia, and signs of gradually progressive stenosis of the larynx, there is moderate fever, slight constitutional disturbance, little or no enlargement of the cervical glands, no albuminuria, and no demonstrable exposure to contagion. The presence of membrane in the pharynx does not stamp the affection as diphtheritic. With reference to this point, the writer holds with the late Dr. Fagge, who believed that in rare cases a diphtheria might begin in and remain limited to the air-passages, but thought it was much more common for a non-specific membranous croup to extend to the tonsils and palate, "leading to the formation of milk-white patches of greater or less extent upon the surface of those parts."

Much of the obscurity which surrounds this subject is due to the indiscriminate employment of the adjective "diphtheritic." German pathologists are in the habit of using this term in its etymological sense.¹ Thus they speak of diphtheritic membranes lining the colon in cases of dysentery, and as being present in the gall-bladder and renal pelvis as the result of the irritation of calculi in these situations. It is manifest that the specific infectious disease diphtheria can have nothing to do with the membranous deposits in such cases, and the fact that such deposits may occur on mucous surfaces as the result of mere mechanical irritation is strongly corroborative of the existence of a non-specific membranous laryngitis.

In doubtful cases the diagnosis may be determined by removing a portion of membrane from the fauces and examining it with the microscope and by culture methods. The absence of the specific organism of diphtheria, the Klebs-Löffler bacillus, would settle the question in favor of the disease being non-diphtheritic.—H.]

PROGNOSIS.—The tendency of this disease is to a fatal result. Of 22 cases analyzed by Ware, 19 proved fatal. Even if the affection be limited to the larynx and uncomplicated, it will destroy life in the great majority of cases if patients be not saved by surgical interference. The danger is of course increased if the affection extend to the bronchial tubes, and in proportion as it extends toward the smaller tubes. Not infrequently broncho-pneumonia exists as a complication, and this of course augments the danger. The duration of the disease in fatal cases is usually from four to six days. In a small proportion of cases it kills in less than four days, or life is prolonged beyond six days. If recovery take place, convalescence is reached after a gradual

¹ It is derived from *dipthēra*, a prepared skin or membrane.

improvement, and is generally slow, the voice remaining more or less affected for a considerable period.

TREATMENT.—Under measures of treatment heretofore relied upon this disease proved fatal in the vast majority of cases. The treatment was based on the supposition that the exudation depends on the intensity of the inflammation, and with a view to reduce this intensity the measures known as anti-phlogistic were actively employed. They have been employed sufficiently to show that they are not successful, and if they do not do good they can hardly fail to do harm. With a view to the proper objects of treatment, it is to be considered that cases are rarely seen prior to the occurrence of exudation, and that the prevention of exudation, therefore, is not the end to which therapeutical measures are to be directed. It is also to be considered that, exudation having taken place, recovery is effected by the separation of the false membrane, and that its separation takes place as a result of a suppurative process beneath it, this process requiring several days. These facts being considered, the rational objects of treatment are to prolong life until the separation of the false membrane can be effected, and to promote the process by which this is effected.

Depletion by bloodletting or other means is not indicated. By reducing the strength of the patient it conflicts with the first object—namely, the prolongation of life. On the contrary, the strength is to be supported, as far as practicable, by concentrated nourishment and the judicious use of alcoholics. Emetics, which have heretofore been used excessively in this disease, are to be employed with circumspection in order not to conflict with the first object. They have been given, and frequently repeated, in order to relieve spasm, and it is undoubtedly true that for a short period after their operation the breathing is comparatively easy; but this end may be attained by other measures less objectionable on the score of depressing the powers of life. Another purpose of emetics is to aid in detaching the false membrane. But it is useless to give emetics for this purpose until the exudation has been loosened by the process of suppuration. Emetics, however, are not to be entirely withheld. In children they compensate for the want of voluntary efforts of expectoration. They may aid in the expulsion of the false membrane when it becomes detached. A fact stated under another head in this chapter is not to be lost sight of—namely, the tolerance of the larynx in young children of an accumulation of mucus sufficient to occasion fatal obstruction. Emetics, then, may be given from time to time, but not too frequently, and the emetic substances used should be those which excite prompt and efficient vomiting without producing prolonged nausea and depression. This will exclude antimony. Ipecacuanha, powdered alum, turpeth mineral, the sulphate of copper, and the sulphate of zinc are among the articles which may be selected. Of these articles, the turpeth mineral acts promptly and efficiently, without much depression or nausea. This remedy was recommended as an efficient emetic in croup forty years ago by Dr. Hubbard of Maine. It is to be borne in mind that the accumulation of mucus in the trachea and bronchial tubes in certain cases furnishes an indication for the use of emetics.

Anodyne remedies are indicated to allay spasm. Opium, however, is to be given with great circumspection. Belladonna and other of the narcotics, if they be found to answer, are to be preferred. Mercury is admissible on the ground stated under the head of Acute Simple Laryngitis; that is, the objections to its use are not to be taken into account in so dangerous a disease as this, so long as there is ground to suppose that it will do any good.

[Calomel and corrosive sublimate are the best preparations of mercury in

this disease, and good results have been claimed for both. The former may be given in doses of from $\frac{1}{4}$ grain to 1 grain every two or three hours and continued so long as it does not excite diarrhœa. Corrosive sublimate or the tincture of iron may be combined in the same prescription, the former in doses of from $\frac{1}{150}$ to $\frac{1}{100}$ grain and the latter in doses of 1 to 5 minims, accordance with the age of the patient.—H.]

In the early part of the disease cold applications to the neck may be tried, as in the treatment of acute simple laryngitis. These, as in cases of the latter form of laryngeal inflammation, have reference, *first*, to lessening the intensity of the inflammation—that is, to an antiphlogistic effect; and *second*, to a sedative effect as regards spasm of the laryngeal muscles. To employ cold efficiently, compresses dipped in ice-water may be applied and removed at intervals of a few moments. The continuance of these applications and their repetition are to be determined by the relief which they appear to afford. They should not be persisted in if the patient resolutely resist them or if they do not seem to give relief.

Topical measures of an opposite character have reference to the second object—namely, promotion of the process by which the false membrane is separated. The neck may be enveloped in a poultice or the water-dressing for the same reason that these are deemed useful in phlegmonous inflammation—namely, to hasten suppuration. But the most efficient topical application is the inhalation of steam, and the best method is to charge the atmosphere of the room with as much of it as possible. In a room at temperature of 80° or 85°, filled with steam, patients are free from spasms and breathe with comparative ease. I have observed cases in which patients passed safely through the disease, the inhalation of steam being the chief measure relied upon.

From the fact that pseudo-membranous exudations are rapidly dissolved in lime-water, the inhalation of spray from lime-water has been resorted to as a means of removing the false membrane from the larynx and trachea, as in cases in which this treatment was successful have been reported. It has proved successful in cases under my observation. Pepsin has been employed for this end. Trypsin, one of the digestive ferments of the pancreas, has recently been used with success.¹ Dr. E. M. Moore recommends the inhalation of the bicarbonate of soda for this object. Slaking quicklime is an effective mode of securing this object, and at the same time of furnishing warm, pleasant vapor. Breathing pure oxygen from time to time, and confining it in abundance in the atmosphere of the room, afford marked relief in dyspnœa.

The topical application of a strong solution of the nitrate of silver has been advocated. The introduction of the sponge probang into the larynx in the child is difficult, owing to the small size of the glottis and frequently want of co-operation on the part of the patient, yet it may be effected. I have witnessed recovery in a case in which this was the chief measure employed. The applications were made twice daily. When the false membrane is loosened, the introduction of the sponge may be useful mechanically in detaching the membrane and pushing it below the glottis, thus leading to its expectoration.

Lastly, the propriety of tracheotomy is to be considered. For statistics bearing on this subject the reader is referred to treatises on the diseases of children. The propriety of the operation hinges, not on the number of cases in which it has proved successful, but on the answer to the question whether lives are saved by it. Now, it cannot be doubted that patients with this disease have been snatched from impending death by opening the trachea.]

¹ Vide *Diseases of Children*, by J. Lewis Smith, 6th ed., p. 581.

is, therefore, not only justifiable, but the practitioner is bound, if possible, not to allow patients to die from suffocation for want of this operation. Of course, the duty of resorting to it is the more imperative the greater the probability of its success; and a fair examination of statistics will show that not a very small proportion of those who would otherwise die may be rescued by it.

The success of tracheotomy depends much on its timely performance. Its failure in many cases is attributable to its having been too long deferred, but it has proved successful repeatedly as a *dernier ressort* under the most unpromising circumstances. As soon as the persisting obstruction—that is, the obstruction due to the exudation, associated perhaps with paralysis of the dilating muscles of the glottis—compromises respiration sufficiently to render it probable that the patient's life will not be prolonged until the separation of the false membrane can take place, the operation is called for. Its success doubtless depends much on the manner of its performance and the subsequent management. (For information on these points the reader is referred to surgical works.)

Sir William Jenner has pointed out an objection to a premature performance of tracheotomy—namely, the effect of the operation on the efficiency of cough. In an efficient act of coughing first a deep inspiration is taken and the glottis closes; then by means of forcible expiratory efforts the current of expired air, dislodging from the bronchial tubes their contents, carries them into the trachea, and, the glottis suddenly opening, expectoration is effected. Now, with an opening in the trachea an efficient act of coughing cannot take place; hence there is a greater liability to accumulation in the bronchial tubes than if tracheotomy had not been performed. The danger from this effect of the operation thus relates to the bronchial tubes in the cases in which bronchitis is associated with the laryngitis.¹

[As to the choice between intubation and tracheotomy there is little to be said in this place, the question being a purely surgical one. The statistics of the two operations are equally favorable. Parents, however, will often consent to the performance of intubation who would object to tracheotomy for manifest reasons. This is a great advantage in its favor. Again, intubation will certainly give immediate relief, and so may pave the way for tracheotomy.—H.]

If operation prove unsuccessful, it diminishes greatly the suffering from obstruction, and is fully justifiable with a view to euthanasia.

Œdema of the Glottis.

This name denotes a serous or, more frequently, a sero-purulent effusion in the submucous areolar tissue above the vocal cords. In the majority of cases, therefore, œdema of the glottis is an inflammatory affection. The effusion is situated chiefly in the ary-epiglottic folds, about the ventricle of Morgagni and the base of the epiglottis. On the vocal cords the mucous membrane is too intimately adherent to the subjacent dense fibrous tissue to admit of submucous effusion. The ary-epiglottic folds and adjacent tissue are swollen, soft, and project from each side as two semi-transparent, gelatinous tumors, as large as, or even larger than, a pigeon's egg, which, lying upon the glottis, are sucked inward with the inspiratory act, and thus occasion obstruction. The current of air in expiration separates and pushes the

¹ Tubage of the larynx, proposed by Bouchut as a substitute for tracheotomy, has been successfully employed by Dr. Joseph O'Dwyer of New York. (Vide *Diseases of Children*, by J. Lewis Smith, 6th ed., p. 589. Vide, also, article by E. Fletcher Ingals, in *Journal of the Am. Med. Association*, Feb., 1886.)

tumors upward, so that in cases of œdema without laryngitis there is little or no obstruction in the expiratory act. Upon cutting into the œdematous tissue a serous or sero-purulent liquid escapes. It is rare for pus-corpuscles to be so abundant that the effusion is distinctly creamy and purulent. In most cases of Bright's disease complicated with œdema glottidis the effusion is thin and watery, with comparatively few blood-corpuscles. The œdema usually exists on both sides, but it is sometimes unilateral. œdema may also occur in the lax submucous tissue just below the vocal cords (subglottic œdema).

When œdema of the glottis is due to inflammation of the mucous membrane in proximity to the seat of the effusion, it is analogous to the subcutaneous œdema which accompanies inflammation of the skin in situations where the areolar tissue beneath is abundant and lax, as, for example, around the eyes and on the penis—the collateral œdema of Virchow. This so-called collateral œdema is, however, always of inflammatory origin.

As causes of œdema glottidis may be mentioned laryngitis, pharyngitis, tonsillitis, retro-pharyngeal and cervical abscesses, injuries to the neck (particularly cut-throat wounds), swallowing irritant poisons, such as ammonia, sulphuric acid, etc., and erysipelatous inflammation of the neck. It also occurs in connection with certain general diseases, especially those complicated with laryngitis, as typhus and typhoid fevers, smallpox, septicæmia, phthisis, heart disease, and both the acute and chronic forms of Bright's disease. It has been attributed to the action of cold. It probably never occurs as an idiopathic affection. It is important to add that it may occur as the first and only dropsical affection connected with disease of the kidneys. Its gravity and the necessity of prompt and efficient interference render it vastly important to appreciate the pathological condition and to recognize its existence.

The occurrence of the œdema may be sudden, and life be destroyed in a few hours or even minutes.¹ In a case occurring in connection with mild pharyngitis the suffering from obstruction was developed during the night, and the patient, leaving his apartment to seek for aid, fell upon the floor, and died before any assistance could be rendered. In a case in which it occurred in connection with tonsillitis the patient was left to sleep in an apartment by himself, there being no difficulty of breathing, and in the night-time a relative in an adjoining room was awakened by his noisy breathing. He was found to be unconscious, and, although medical aid was promptly called and the trachea opened without delay, the operation was too late to prevent a fatal result.

Difficulty of breathing, due to obstruction at the glottis, is a prominent symptom. This is associated with a sense of a foreign substance at the seat of the obstruction, and a strong disposition to hawk and swallow. The diagnostic point relating to the difficulty of breathing is, the inspiratory act is alone or chiefly obstructed, expiration being free. The inspiration is arrested before it is completed, being, as it were, suddenly cut short, and both the inspiration and expiration are accompanied by marked stridor. If laryngitis do not coexist, the voice is devoid of hoarseness or huskiness. This will serve at once to exclude laryngitis. I have met with a case, ending fatally, in which there was no hoarseness or huskiness of the voice and no appearance of laryngitis after death. The diagnosis may be made positive by means of the touch. With the forefinger introduced into the mouth, carried to the base of the tongue and applied below the epiglottis, the œdematous tumors may be distinctly felt.

If the embarrassment of breathing be not too great to permit a satisfactory

¹ A case is reported in *Guy's Hospital Reports*, April, 1855, which terminated fatally within five minutes after difficulty from obstruction was experienced.

laryngoscopic examination, this will render the diagnosis positive. The tumors may sometimes be seen by depressing the tongue, without the aid of the laryngoscope.

Statistics have heretofore shown a large fatality. Bayle found that in 17 cases only 1 recovery took place. Of 40 cases collected by Valleix, 31 were fatal. Of 168 cases collected by Sestier, 127 died. With a correct appreciation of the pathological condition, a prompt recognition of it, and timely surgical interference, many, if not most, patients may be saved. It is fair to attribute the large proportion of fatal cases heretofore to an imperfect knowledge of the affection, or delay in the diagnosis, or want of promptness in resorting to efficient interference.

The affection kills by apnoea. The object of treatment is to prevent suffocation, and if the obstruction be sufficient to occasion much labor of breathing, lividity, etc., no time is to be lost in efforts to obtain relief by medication. Either the larynx or trachea must be opened, or the method of scarification, as practised by Dr. Gurdon Buck, must be resorted to. Buck's method consists in introducing a curved bistoury, properly guarded, into the mouth, carrying it below the epiglottis guided by the left index finger, and scarifying on both sides, so as to give exit to the effused liquid. The scarification may be repeated if required.¹

The difficulty in the way of the performance of this operation is greater than might be supposed. The increase of suffocation caused by introducing the fingers into the mouth, the movements of the larynx incident to the labored breathing, and the acts of vomiting which are excited, render it not easy to deliberately scarify the œdematous parts. In a case under my observation the result was unfortunate. The tumors were not sufficiently scarified, but wounds were made which led to hemorrhage and the flow of blood into the air-tubes. Tracheotomy was subsequently performed, but too late to save the patient. This case is referred to in order to enforce the importance of being prepared to meet with more difficulty than might be anticipated. Without assuming to adjudicate in a matter which is purely surgical, I am led to think that the simpler as well as the more effectual operation is to open the larynx or trachea. Niemeyer stated that in some cases the finger-nail will suffice to open the œdematous tumors. Strong pressure with the finger has succeeded.

A case at Bellevue Hospital exemplified the importance of opening the trachea before the obstruction threatens immediate death. A patient was suffering considerably from difficulty of breathing, but, as was decided, not sufficiently to require laryngotomy. The house physician, however, made every preparation to perform the operation at an instant's notice. Suddenly the difficulty of breathing increased, and the physician was in a few moments at the bedside, but too late to save the patient. The liability to a very rapid increase of obstruction proving quickly fatal is to be considered in deciding upon the propriety of opening the larynx or trachea. The operation may be advisable, as a precautionary measure, even if life be not at the moment threatened, when the practitioner cannot remain with or near the patient until danger is passed. In the event of a physician being summoned to a case in which life is momentarily in danger, and when appropriate surgical instruments are not at hand, the larynx or trachea should be opened at once, without dissection, with a pocket-knife.

Edema of the glottis rarely occurs in infancy or childhood, the reason probably being that the areolar tissue at the situation where the œdema occurs is less abundant and loose in young subjects than after puberty. The period

¹Vide *Trans. Am. Med. Association*, vols. i. and iv. Several cases successfully treated by this method are reported by Dr. Buck. Cohen (*op. cit.*) has used with success, for scarification, a common gum-lancet.

of life in which it is most liable to occur is between the ages of twenty and forty. It occurs much oftener in men than in women.

Œdema in very rare instances occurs below the vocal cords. This is distinguished as subglottic œdema. Its occurrence in this situation is not determinable by the touch. The diagnosis can only be made by means of the laryngoscope. Scarification is not practicable. Tracheotomy is indicated under the same circumstances as in cases of obstruction from œdema above the cords. The obstruction calls for this operation, although the diagnosis of subglottic œdema may not have been made.

Spasm of the Glottis.

Spasm of the muscles closing the glottis is an important element in most of the affections of the larynx which have been considered. To this element are attributable the croupal cough and the paroxysms or exacerbations of dyspnoea in simple acute and subacute laryngitis in children and in laryngitis with fibrinous exudation. But spasm occurs also as a purely functional affection; that is, irrespective of inflammation or lesion within the larynx. It is an element of several of the functional affections of the nervous system (neuroses) to be hereafter considered—namely, hysteria, epilepsy, epileptoid convulsions, rabies, and tetanus. Occurring irrespective of these connections, it may be reckoned among the functional affections of the larynx.

Spasm occurs in young children, affecting the respiration without inducing cough. This is the pathological condition when the infants are said to have fits of "holding the breath." Respiration is arrested until the face becomes congested and livid, and when the spasm relaxes the inspiration may be sonorous, as in pertussis. In some children these paroxysms occur more or less frequently. They are sometimes accompanied by carpo-pedal spasm. Convulsions may occur. Death may take place in a prolonged paroxysm or in consequence of repeated paroxysms in rapid succession. I have known an instance of this kind. The affection is commonly known as *laryngismus stridulus*. From a fancied connection with enlargement of the thymus gland persisting after birth, it has been called *thymic asthma*.

This affection is purely neurotic. It involves a peculiar susceptibility to spasm in the laryngeal muscles. This susceptibility may be incident to a certain period, as during weaning or dentition, but in some cases it appears to be an idiosyncrasy of infantile life. When the predisposition exists, paroxysms are liable to be excited by various causes acting physically and mentally. This susceptibility is sometimes observed in different children of the same family—a fact in confirmation of its innateness. [Rickets and scrofula are powerful predisposing factors. The statement has been made on good authority¹ that probably nine-tenths of the children who suffer from this affection are rachitic.—H.]

During a paroxysm it is customary to employ means to produce a strong impression on the surface, as slapping the back or sprinkling cold water on the face. A ready and effective mode of arresting a paroxysm is to introduce a finger into the throat. The treatment otherwise involves the removal of all local causes of irritation, such as the distension of the gums and the retention of fecal matter, avoidance of causes inducing mental excitement, and measures to invigorate the system.

Spasm of the glottis occurring in children over two years of age, accompanied by laryngeal irritation and cough, is a frequent affection, known as *spasmodic croup*. A child is suddenly attacked during the night, having

¹ That of Eichhorst.

perhaps gone to bed apparently in perfect health. The breathing is labored and sonorous; the cough presents in a marked degree the shrill, ringing, croupal character. Great alarm is produced, and the physician is sent for in urgent haste. The surface of the body is cool; the pulse is small and perhaps not accelerated; the voice or cry is not hoarse nor husky as in laryngitis; the affection, in short, is purely spasmodic. It is unattended by danger. When the violent symptoms are relieved respiration is found to be unobstructed. There is no liability to its eventuation in so-called true croup; that is, to laryngitis with fibrinous exudation. It is to be discriminated from the latter affection. The points involved in this discrimination are as follows: The abruptness of the attack, which is not preceded by symptoms denoting laryngitis; the violence of the attack, in this respect differing from so-called true croup; the absence of hoarseness or huskiness of the voice, of febrile movement, and of fibrinous exudation in the pharynx; and, finally, the speedy and complete relief. The paroxysms may recur for two or more successive nights.

The TREATMENT consists of a mild emetic if there be reason to suppose that the stomach is overloaded, a hot foot-bath, and warm fomentations to the neck. These measures are uniformly successful. The treatment of these cases is sometimes needlessly active, under the impression that a serious affection is threatened; and practitioners are apt to congratulate themselves and the friends of the patient on their success in preventing true croup.

Spasm of the glottis may occur as a functional affection in the adult. It is occasionally incidental to hysteria, and may simulate, as regards some of the symptoms, laryngitis or œdema of the glottis. The diagnostic points are as follows: The coexistence of hysterical phenomena; the absence of huskiness or hoarseness of the voice; intermittency of the difficulty of breathing; the speedy relief obtained by anodyne remedies; and the sudden development of the affection. I have been consulted in several cases in which spasm of the glottis occurred in male adults without any evidence of disease within the larynx or of intrathoracic disease.

The measures of treatment are anodyne or antispasmodic remedies for immediate relief, and afterward those indicated by the general condition and those employed in analogous nervous affections.

Spasm of the glottis may be occasioned by irritation of the recurrent laryngeal nerve from the pressure of a tumor or other causes. It is one of the symptoms of aortic aneurism, and, occurring in a person over forty years of age, it should always excite a suspicion of aneurism. I have reported a case of aortic aneurism in which the life of the patient was destroyed by frequently recurring paroxysms of laryngeal spasm.¹

Nervous Cough.

The term "nervous cough" is used to designate a neuropathic disorder characterized by a dry, peculiar cough occurring without laryngitis, bronchitis, or any pulmonary affection. It may be noticed with propriety among laryngeal affections, inasmuch as the distinctive character of the cough relates to the larynx. In most of the cases which I have seen the cough has had a peculiar barking tone, and the pitch has been low, showing that the glottis was dilated at the instant of coughing. In some cases, however, the tone is

¹ *American Medical Times*, 1865. Another similar case has fallen under my observation. It is questionable whether in these cases the attacks of laryngeal obstruction be not due to paralysis of the abductor muscles. This inquiry will be referred to in connection with Aortic Aneurism.

shrill and the quality of sound croupal, showing spasm of the glottis. In a case recently under observation the cough consisted of a single, short, hoarse bark, often repeated several times in a minute. The cough is sometimes in paroxysms, having a resemblance to whooping cough. The peculiar sound of the cough, together with its frequent recurrence and sometimes its violence, renders it distressing to those whose sympathies are excited, and annoying to others. Cohen, who observed the movements of the glottis in a well-marked case by means of the laryngoscope, states that the vocal cords came together with force, and suddenly separated at the instant of the cough.

This disorder rarely occurs in males. It is often associated with more or less of the symptoms embraced under the name hysteria. The cough has been called *tussis hysterica*, and it is usually included by medical writers among the diversified hysterical manifestations. It occurs chiefly in chlorotic girls. I have known it to occur before the age of puberty. It is likely to persist for a considerable period.

The DIAGNOSIS is to be based on the peculiarity of the cough, its dryness—except that the acts of coughing, if frequent and violent, may occasion some mucous expectoration—and the negative result of careful physical explorations of the chest. The diagnosis is strengthened, on the one hand, by the coexistence of anæmia and of hysterical phenomena, and, on the other hand, by the absence of rational symptoms pointing to phthisis. The laryngoscope should be employed in order to render positive the exclusion of other laryngeal affections.

The indications for TREATMENT relate to anæmia if it exist, and to other morbid conditions affecting the nervous system. Tonic remedies, a nutritious diet, out-door life, and, in short, invigorating measures, are indicated. In addition to chalybeates may be mentioned quinia, small doses of strychnia, and the preparations of zinc as appropriate remedies. Hygienic measures, however, are of the first importance. A change of climate is sometimes advisable if other measures fail. A sea-voyage proved effective in a case under my observation after a long persistence of the cough in spite of various measures of treatment. As palliatives for the cough antispasmodic remedies may be prescribed, but opiates are not advisable.

This is one of the affections which may be induced by involuntary imitation. Cohen states that within his knowledge a school for girls was suspended in consequence of the large number of cases.

Nervous Aphonia—Paralysis of Laryngeal Muscles.

Loss of voice, or aphonia, is incidental to the varieties of laryngitis which have been considered. But it occurs when not dependent on either inflammation or lesions within the larynx; in other words, as a functional affection. It is then known as nervous aphonia. The loss of voice is due to paralysis affecting the nerve of phonation—namely, the spinal accessory. The affection may be limited to the voluntary movements of the laryngeal muscles, the reflex movements involved in respiration being unaffected.

Functional aphonia is met with not infrequently in women, and is often, but not always, associated with phenomena embraced under the name hysteria. As a purely neurotic affection—that is, not dependent on any lesion of the nervous system—it is extremely rare in the other sex. An obvious distinction is between loss of voice and loss of speech, or aphasia. Aphonia may occur from pressure on the recurrent laryngeal nerve by an aneurismal or other tumor, and the loss of voice should direct attention to this as a possible or probable cause.

The DIAGNOSIS of nervous aphonia may be made by attention to the charac-

ter of the whispered voice. The patient speaks in a pure, soft whisper, without effort. On the contrary, if the aphonia be due to laryngitis, the whisper is stridulous or husky and labored. Moreover, in aphonia due to laryngitis there is more or less cough and expectoration, symptoms generally absent in nervous aphonia. As the question is usually to decide between nervous aphonia and chronic laryngitis, and as the latter affection is generally associated with pulmonary phthisis, the absence of the symptoms and signs of the latter disease will serve to confirm the diagnosis. Examination with the laryngoscope will establish the diagnosis by showing that the larynx is free from lesions; and the absence or the incompleteness of movements of the glottis when an effort to speak is made may be ascertained by inspection.

Inspection with the laryngoscope shows that paralysis of laryngeal muscles may be bilateral or unilateral, and that the different muscles—namely, the adductors and abductors, the tensors and the laxators—may be affected separately. Unilateral paralysis of course points to some cause affecting the pneumogastric nerve on one side only, and it is especially suggestive of an aneurismal tumor pressing upon one of the recurrent laryngeal nerves. Bilateral paralysis, however, may be caused by pressure upon the recurrent laryngeal or the vagus nerve on one side. A case under my observation exemplified the correctness of this statement.

The localization of paralysis in the different muscles of the larynx, singly or severally, is to be made by laryngoscopic examination. As a rule, in functional aphonia the adductor muscles are affected. The patient is unable by an effort of the will to approximate the vocal cords sufficiently for phonation. In paralysis of the abductor muscles the voice is more or less affected. This form of paralysis will claim separate notice. (For an account of the laryngoscopic appearances, the symptoms, etc. of paralyzes affecting the different muscles separately, the reader is referred to works which treat of diseases of the larynx *in extenso*.¹)

If aphonia be purely neurotic—in other words, involving no lesion of the nervous centres or pressure on either the par vagum or the recurrent laryngeal nerve—recovery may be expected after a duration of the affection varying much in different cases. The voice is sometimes restored instantaneously and unexpectedly. I have met with cases in which repeated attacks had occurred.

TREATMENT in these cases should be directed to the general condition. Tonic remedies and invigorating hygienic measures are indicated. Moderate counter-irritation may be useful. Electrization of the laryngeal muscles has been found signally useful. Both the induced and the direct current are used with success. The recovery of the voice sometimes follows a single application or even a single electrical shock; but in some cases the treatment to be successful must be continued for several weeks. In some of the cases in which electricity at once effects a cure there is reason to think that the success is due to a moral influence. Other measures often effective are evidently operations through the mind. Cohen states that he has repeatedly effected a cure by the use of the laryngoscopic mirror, the patient being led to suppose that its introduction was a curative procedure. The late Professor Ware sometimes succeeded by telling patients that they could recover the voice by an energetic act of the will. A violent mental emotion has sometimes produced sudden aphonia, and, aphonia existing, has sometimes occasioned a sudden restoration of the voice.

Whenever there is a partial restoration of the voice complete recovery may be expected by systematic efforts of speech, in the same way as the control of the will over other paralyzed muscles is effected by means of persistent vol-

¹ Cohen, *op. cit.*, treats fully of laryngeal paralyzes.

untary exercise. Beginning with the vowels most easily spoken, the practice should extend to those more difficult of utterance, then to consonants and words of one syllable, and finally to sentences. After recovery the exercise of the voice within the limit of fatigue is to be advised.

Aphonia is sometimes feigned. The malingerers are women actuated by a desire to excite sympathy or to become objects of interest. I have met with two cases in which the patients declared their inability even to whisper. One of these patients communicated by signs and by writing, and the other by silent, inarticulate movements of the lips. A curious feature in the first of these cases was that during a second visit, accompanied by her husband, while I was in conversation with him, she began to speak in a low voice and took part in the conversation during the remainder of the interview. No comment was made on this sudden recovery of voice either by herself, her husband, or by me. I met her casually some years afterward; there was then no impairment of voice, and she made no reference to her aphonia except to ask if I recollected her consulting me. The subsequent history in the other case is unknown. That the inability to speak is in some instances a self-delusion is probable. This may have been the explanation in the cases just noticed.

Paralysis affecting the abductor muscles has important distinctive features when contrasted with the paralysis of the adductors. The effect of bilateral paralysis of the abductors is the approximation of the vocal cords, giving rise to more or less obstruction of respiration. The obstruction is manifested especially in inspiration. The condition is analogous to that observed after the physiological experiment of dividing both recurrent laryngeal nerves. The vibration of the cords with the current of inspired air causes stridor. There is dysphonia, but not complete loss of voice. Dyspnoea exists in proportion to the obstruction. There is danger of death from suffocation, especially if, as may happen, spasm of the adductors be added to the paralysis of the abductors.

In view of the indication for prompt treatment whenever the obstruction is sufficient to involve danger, the diagnosis is extremely important. The laryngoscope renders it positive, and it cannot be made so otherwise than by inspection of the larynx. In marked cases the vocal cords are in close proximity, the aperture being reduced to a narrow slit, and no dilatation takes place in the act of inspiration. Without a laryngoscopic examination the noisy, stridulous, inspiratory sound might suggest either laryngitis or œdema of the glottis.

Tracheotomy is indicated whenever the obstruction involves immediate danger. The indication derives great force from the fact that with an opening into the trachea the affection is tolerated indefinitely. Cohen cites a case within his cognizance in which a tracheal tube had been worn for more than twelve years, the patient a judge who was able to continue his duties on the bench. He also cites three cases in which life was lost from a refusal to submit to the operation of tracheotomy. If, from the occurrence of spasm of the adductors, paroxysms be liable to occur threatening life, there can be no doubt concerning the propriety of tracheotomy as a prophylactic measure, provided the patients be not under constant observation.

Cases in which spasm of the adductors is not an element may not require surgical interference. A case came under my observation at my college-clinic in which recovery took place without an operation, the treatment consisting chiefly of quietude and *asafoetida*. Dr. George M. Lefferts has reported two cases of recovery without tracheotomy under the use of the iodide of potassium, the patients having had syphilis.¹

¹ *New York Med. Journal*, Dec., 1878.

The PROGNOSIS as regards recovery from the paralysis will depend on the causative conditions. If the paralysis depend on lesions, either centric or peripheral, which are permanent, recovery is not to be expected. Danger of death from obstruction is permanently averted by a tracheal opening. If, however, the paralysis be functional, or if it depend on syphilitic changes, as in the cases reported by Lefferts, the prognosis as regards recovery is favorable.

If the paralysis be unilateral and remain so, there is little or no danger from obstruction. The voice is weak and stridulous, simulating chronic laryngitis. In a patient forty years of age aneurism of the aorta should always be suspected, and should be sought for, especially in the site of the descending portion of the arch; but the paralysis may depend on other causes, either centric or peripheral, generally the latter. An enlarged bronchial gland, carcinoma of the œsophagus, and a mediastinal tumor may cause unilateral paralysis by pressure on the recurrent laryngeal nerve.

Bilateral paralysis of the abductor muscles is extremely rare. The number of reported cases is small; but it is probable that the pathological character of the affection was not infrequently overlooked prior to the date of laryngoscopy.

Morbid Growths.

The most common tumor within the larynx is papilloma. It takes its origin by preference from that portion of the laryngeal mucous membrane which is covered with flat epithelium. It may have a broad base or may be connected with the mucous membrane by a distinct pedicle. It consists essentially of hypertrophied and newly-formed papillæ covered with flat epithelium. Small papillomatous growths are not infrequent attendants upon tuberculous and syphilitic laryngeal ulcers and chronic laryngitis. Papillomatous growths, however, may occur without inflammation. Other important forms of new growths are the laryngeal polypi, which may be fibrous, myxomatous, or glandular. Fibroma, myxoma, and adenoma do not, however, necessarily assume a polypoid form in the larynx. Carcinoma of the larynx, when primary, is usually of the flat-celled variety, and takes its origin from that portion of the larynx lined with squamous epithelium, especially from the true vocal cords. Cancer seated primarily in the larynx is rare, the disease, in the cases in which this part becomes affected by it, generally originating in the œsophagus or in the neck exterior to the larynx. Syphilitic and tuberculous new formations have already been referred to. A detailed consideration of these and other rarer forms of laryngeal tumors must be sought in works treating specially of diseases of the throat.

Morbid growths occasion inconvenience, suffering, and death by producing obstruction. Surgical interference becomes necessary when the obstruction is sufficient to endanger life. A tube may be worn in the trachea for an indefinite period. In a case in which a permanent artificial opening becomes advisable, it may be a question whether a large fistulous orifice might not be established, rendering the tracheal tube unnecessary. As bearing on this question, the following case is of interest: A patient, aged about forty, admitted into one of my wards in Bellevue Hospital and suffering from the effects of a debauch, had a fistulous orifice in the anterior portion of the trachea large enough to admit the end of the forefinger. This fistula followed a wound received in a fracas, and had existed for seventeen years. It occasioned little or no inconvenience in respiration. There were no symptoms of inflammation or irritation of the trachea or bronchial tubes, and he was entirely free from pulmonary disease; the only inconvenience which it occasioned was in

speaking. In order to direct a current of air through the glottis sufficient for the production of the voice, he was accustomed to approximate the chin to the sternum, and in this way he was able to close the fistula.

The laryngoscope has proved to be of great practical value in determining the existence, situation, size, and character of morbid growths within the larynx, and in facilitating surgical operations for their removal through the laryngeal aperture. Cohen states that prior to laryngoscopy probably not more than seventy cases of morbid growths within the larynx were to be found in medical literature, whereas within the last twenty years thousands of such cases have been reported.

The larynx has been extirpated for the removal of carcinoma, and an artificial larynx has been substituted. The first operation of this kind was performed successfully by Billroth. (Surgical works are to be consulted for this and other operative procedures for tumors of the larynx.)

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

PERICARDITIS.

Introductory Remarks.—Acute Pericarditis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Chronic Pericarditis.—Pneumo-Pericarditis.

DISEASES affecting the circulatory system are seated either in the blood-vessels or in the central organ of the circulation—the heart. There is a group of affections existing independent of the organs of the circulatory system and involving certain morbid changes of the blood. The affections belonging in this group are simple or benign anæmia, chlorosis, leucocythæmia, pseudo-leucocythæmia, lymphatic anæmia, or Hodgkin's disease, pernicious anæmia, and to these may be added Addison's disease. These affections proceed from defect or disturbance referable to the blood-producing organs. They will be considered in a separate section (Section III.), under the heading *Diseases Affecting the Hæmatopoietic System*. Diseases of the vessels, entering, as they do, much more largely into maladies which belong to the surgeon than into those which fall within the province of the physician, are fully considered by surgical writers. Of the diseases of the arteries, aneurisms situated within the chest and abdomen will alone claim attention in this treatise. Thoracic aneurisms will be noticed in this section, and those situated within the abdomen will be referred to in connection with abdominal tumors in Section IV. This section will be devoted chiefly to diseases affecting the heart.

The diseases of the heart are conveniently arranged in the following groups: 1. Inflammatory affections; 2. Structural lesions; 3. Functional disorders. Inflammation affecting the heart gives rise to different diseases according to the structure in which it is seated. Inflammation of the serous membrane investing the heart (the pericardium) gives rise to the disease called *pericarditis*. Inflammation of the membrane lining the cavities of the heart (the endocardium) is another disease, called *endocarditis*. Inflammation of the substance of the heart (the myocardium) is distinguished as *myocarditis*. These three inflammatory diseases claim separate consideration.

Acute Pericarditis.

Pericarditis occurs as an acute and as a chronic affection. Acute pericarditis will be now considered, and afterward the chronic form of the disease.

ANATOMICAL CHARACTERS.—Acute pericarditis may be either diffuse or circumscribed. When circumscribed, the inflammatory products are usually deposited at the base of the heart, near the origin of the great vessels. Diffuse pericarditis is the usual form. The morbid appearances resulting from acute inflammation in this situation are essentially the same as in inflammation of other serous membranes—for example, the pleura. The serous membrane is at first reddened in consequence of congestion and small ecchymoses. The inflammatory exudation consists of fibrin, serum, pus-cells, and red blood-corpuscles. In the majority of cases it is sero-fibrinous, the pus-cells not being sufficient in number to render opaque the fluid part of the exudation. The exudation may consist almost wholly of fibrin, with very little serum. This has been called dry pericarditis. Under exceptional circumstances the red blood-corpuscles are present so abundantly as to give to the serum a reddish or brownish coloration. This constitutes hemorrhagic pericarditis. It occurs especially in connection with tuberculosis or cancer of the pericardium and also as a complication of scorbutus. Tuberculous pericarditis may occur, although very rarely, without tuberculous deposits in any other part of the body. In rare instances the exudation is purulent. This may occur in pyæmia and in consequence of the extension of a purulent inflammation in the neighborhood, as in cases of suppurative pleuritis, hepatic abscess, etc. In acute diffuse pericarditis the fibrin is deposited in the form of a layer or a series of layers on the visceral and on the parietal surface of the membrane. It is a peculiarity of this fibrinous pseudo-membrane that its free surface has a rough, shaggy appearance, due to the projection of a number of filaments and villous processes (*cor villosum*, hairy heart). This peculiar disposition is attributable to the constant churning action of the heart.

The quantity of liquid effusion in different cases of pericarditis varies greatly, amounting in some cases to a few ounces only, and in other cases to a pint or more. It is usually of a yellowish color, and contains flocculi of fibrin. Wandering cells or pus-cells are present in the fibrinous layer and in the serum, also in varying numbers in the tissue of the serous membrane itself. Whether these have any other origin than emigration from the blood is still a matter of dispute.

If recovery take place, the serum is absorbed; the fibrin undergoes a molecular disintegration, and is absorbed. At the same time new connective tissue in the form of adhesions is developed. The process of their formation is the same as in pleurisy (p. 25). The pericardial sac may be completely obliterated by the firm adhesion of its two layers, or it may be partially obliterated. The adhesions may also develop in the form of threads and bands stretching between the pericardial surfaces.

Purulent pericarditis runs a less favorable course. Several pints of pus may accumulate in the pericardial sac. It sometimes happens that the parietal layer of the pericardium ulcerates, and the pus may even escape externally by a fistulous opening. It is possible for only small accumulations of pus to be absorbed.

The muscular substance of the heart suffers more or less in its nutrition in all cases of pericarditis. The most frequent change is parenchymatous and fatty degeneration of the muscular fibres situated just beneath the pericardium. The fibrous thickening of the visceral pericardial layer which follows pericarditis is sometimes accompanied by the growth of fibrous tissue into the subjacent muscular substance, and a consequent atrophy of the muscular fibres in this situation.

The most convenient mode of dividing acute diffuse pericarditis into stages is the same as that adopted in pleuritis. The first stage extends to the time

when liquid effusion takes place to an extent sufficient to be appreciated by the physical signs. The second stage, or the stage of effusion, continues until the liquid is absorbed. The third stage extends from the absorption of the liquid to the recovery, and this is generally the stage of convalescence.

CLINICAL HISTORY.—The symptoms are almost invariably made up, to a greater or less extent, of those arising from coexisting affections; for in the great majority of cases the disease is associated with articular rheumatism, Bright's disease of the kidneys, or pleuritis with or without lobar pneumonitis. Under these circumstances it is not always easy to determine to what extent certain symptomatic phenomena are due to the cardiac disease. As a rule, the development of the inflammation is attended with more or less pain, which in some cases is acute and lancinating, like the pain in pleuritis, and increased by forced breathing, so that the disease has not infrequently been supposed to be inflammation of the pleura. The intensity of the pain varies much in different cases; it is not always a prominent symptom, and it is sometimes slight or even wanting. The pain may be increased by acts of deglutition, by eructations, and it sometimes is analogous to that in angina pectoris. The facies is that of suffering and anxiety. A dry, irritable, suppressed cough is generally present. Tenderness over the præcordia is more or less marked, and pressure in the epigastrium upward in a direction toward the heart sometimes occasions acute pain. The pain produced by a deep inspiration may cause the patient to shorten this act, and hence, by way of compensation, the number of respirations per minute is increased. The *alæ nasi* may dilate in inspiration. Patients sometimes manifest suffering from an indefinite sense of distress, without acute, localized pain, and in women hysterical phenomena may be associated with the development of the disease. The action of the heart is increased, amounting sometimes to palpitation. The pulse is more or less accelerated, quick, and vibratory. Pyrexia and its concomitants—namely, anorexia, debility, etc.—are present. These are symptoms belonging to the first stage.

The duration of the first stage is usually short. An appreciable amount of effusion may take place in a few hours, and it is rarely delayed beyond one or two days. The acuteness of the local symptoms—namely, pain and soreness—then diminishes, and if the amount of liquid effused be sufficient to fill or distend the pericardial sac, symptoms are added which proceed from the pressure of the liquid upon the heart. These symptoms are—a sense of oppression referable to the præcordia; a tendency to syncope on exertion, which leads the patient to refrain as much as possible from movements of the body; feebleness and irregularity of the pulse, with a notable increase on emotional excitement or any muscular effort; dyspnoea, sometimes amounting to orthopnoea if the accumulation of liquid be large and rapid; feebleness of the voice or even aphonia; and dysphagia, in some cases produced by pressure of the distended sac on the recurrent laryngeal nerves and on the œsophagus. Cyanosis and turgescence of the cervical veins are sometimes marked, due probably to pressure on the auricles and the *venæ cavæ*. Venous pulse on the neck is sometimes observed. Vomiting is an occasional symptom. Singultus may be produced by pressure on the phrenic or branches of the pneumogastric nerve. Some cases are characterized by remarkable disturbance of the nervous system. Mental aberration, consisting in obstinate taciturnity and indifference, alternating with paroxysms of maniacal excitement under the influence of delusions which excite terror, is occasionally observed. Coma, chorea, and tetanic convulsions have been known to occur. These symptoms are likely to mask the cardiac disease and lead the practitioner to suspect disease of the brain. Autopsical examinations show that in these

cases neither inflammation nor any appreciable lesion of the nervous system exists, and hence the phenomena are to be referred to functional disturbance of the nervous system.

The severity of the disease, as denoted by the symptoms, corresponds to the intensity of the inflammation and the amount of effusion. If the inflammation be slight or moderate and the quantity of effused liquid small, the disease may run its course without any symptoms denoting gravity, and the symptoms may not even point to the existence of any affection within the chest. In other cases it is one of the most distressing and formidable of diseases. The symptoms due to compression of course diminish as the liquid is absorbed. The absorption sometimes goes on very rapidly, and in this respect different cases present great variations. If, instead of being absorbed, the liquid continue to accumulate and life be not rapidly destroyed, the pericardial sac may become greatly dilated and the affection become chronic. The rapidity and completeness of recovery after absorption will depend on the amount of inflammatory exudation. This may be too abundant to be absorbed, and the disease may end fatally after continuing for a greater or less period in a chronic form. In cases which go on favorably toward recovery the action of the heart is feeble and easily excited during the stage of convalescence.

PATHOLOGICAL CHARACTER.—Acute pericarditis does not differ essentially in character from other serous inflammations. The same series of processes which take place in the serous inflammation considered in the preceding section (Pleuritis) occur in this inflammation—namely, fibrinous exudation and liquid effusion, agglutination followed by permanent adhesion of the free surfaces of the membrane, and sometimes the formation of pus. Suppurative pericarditis, however, occurs in a much smaller proportion of cases than suppurative pleuritis, or empyema. As in cases of pleuritis and other serous inflammations, so in different cases of pericarditis, both the actual and relative amount of fibrin and serum differ greatly. In some cases the quantity of fibrin is small and the effusion of liquid abundant; in other cases the fibrin is abundant with but little liquid; and, again, in other cases both fibrin and liquid are either abundant or small. Judging from the number of cases which I have seen, *dry* pericarditis—that is, the presence of fibrin without serous effusion—is not extremely rare.

CAUSATION.—Acute pericarditis may be produced traumatically by perforating wounds of the chest or contusions. In one of the cases which I have observed it was produced by a wound inflicted by a one-tined fork. Walshe refers to a case in which the pericardial sac was perforated in the juggler's trick of swallowing a sword, and fatal pericarditis was induced. In the museum of Bellevue Hospital is a remarkable specimen in which a set of false teeth is contained within the pericardial sac. The teeth were swallowed during alcoholic coma, and, lodging in the lower part of the œsophagus, produced ulceration through this tube and into the pericardium, giving rise to fatal pericarditis.

Exclusive of its traumatic origin, the disease is almost always secondary, and it is developed in the course of acute articular rheumatism oftener than in connection with any other affection. Occurring in the course of rheumatism, it is distinguished as rheumatic pericarditis. It would appear, from statistical data, to occur in cases of acute rheumatism in a proportion of about 1 to 6. Sibson, out of 326 recorded hospital cases under his care, found evidence of pericarditis in 63.¹ Without having noted sufficient data

¹ *Reynold's System of Medicine.*

for analysis, I am sure that this proportion is considerably higher than in my experience. The comparative infrequency of this complication in the cases which have come under my observation I am disposed to attribute to the prompt and efficient employment of the alkaline treatment which for many years has been in vogue in this country. Generally, the development is in the early part of rheumatism, after a greater or less number of the joints have been affected, but occasionally the pericarditis precedes the articular affection. When it follows the affection of the joints, it is not due, as was formerly supposed, to a metastasis of the articular affection, but it proceeds from the same morbid condition which underlies the latter. Rheumatic pericarditis is generally associated with endocarditis. The latter existed in 54 of the 63 cases analyzed by Sibson.

Next in frequency to its development in the course of rheumatism, it occurs in connection with either acute or chronic disease of the kidneys. It is not very infrequent in cases of chronic Bright's disease; but it is a rare concomitant of the renal affection which follows scarlatina and in other cases of acute diffuse nephritis. It occurs most frequently with the small kidney of chronic Bright's disease. Sibson's statistics show that it occurs in as many as 8 or 9 per cent. of all fatal cases of Bright's disease.

Pyæmia, scorbutus, the continued and eruptive fevers, erysipelas, and influenza are other affections in connection with which this disease has been observed to occur. It is a not very infrequent concomitant of pleuritis and of pneumonitis, affecting either the right or left lung—oftener the latter. Pericarditis may be secondary to peritonitis and to inflammation in the mediastinum. [It is believed by most modern pathologists to be always due to the direct action of micro-organisms. Like pleurisy, however, it may be caused by more than one organism. For example, in pericarditis secondary to pneumonia the pneumococcus has been found in the products of pericardial inflammation, while in other cases streptococci and staphylococci have been the only organisms detected.—H.]

I have met with a few cases in which a careful examination failed to discover any pre-existing or coexisting disease, nor was any other affection developed so long as the patients remained under observation, the periods extending only to the time when they had recovered sufficiently to leave the hospital. The extreme infrequency of such cases renders it extremely probable that whenever pericarditis exists some one of the affections just named will be found associated with it.

DIAGNOSIS.—The events belonging to the clinical history of acute pericarditis are not sufficiently diagnostic for the disease to be discriminated, by the symptoms alone, from pleuritis, pneumonitis, or pleurodynia. Its coexistence with the two former of these affections could not be ascertained, and its existence would surely be overlooked in the cases in which the symptoms are but little marked. The diagnosis must rest on physical signs. The presence of inflammatory exudation gives rise to an adventitious sound or murmur caused by the rubbing together of the pericardial surfaces in the movements of the heart. This sign is proof of the existence of pericarditis, and, as the exudation takes place usually within a few hours after the beginning of inflammation, the sign becomes available for diagnosis at an early period of the disease. The sign is called the *pericardial* or *cardiac-friction murmur*, or sometimes, in contradistinction from the murmur produced by blood-currents within the heart, an *exocardial murmur*.

The friction murmur is to be distinguished from the murmur produced within the heart, called *endocardial* or *bellows murmur*, by attention to the following points: It is double; that is, consisting of two adventitious sounds

for each beat of the heart, one produced by the systolic and the other by diastolic cardiac movements. The character of the murmur denotes friction, that is, it is rubbing, grazing, or grating, and at a later period in the disease it may be creaking, like the sound of new leather. It is limited to the præcordia, not propagated beyond the borders of the heart, and it may be limited to a portion of the præcordial space. As regards its intensity, it differs much in different cases, and it may vary in the same case during an examination, the variations being dependent on the force of the heart's action. It has not the same fixed connection with the normal heart-sounds as have the endocardic murmurs; in other words, it does not observe the same regularity in rhythm as the latter. This is a striking point of distinction. It is intensified, and sometimes changed in character, by firm pressure with the stethoscope. In connection with a rough friction murmur, fremitus is sometimes felt by the hand applied to the præcordia.

A friction murmur, if ever wanting in the first stage of pericarditis, is present so generally that we are warranted in basing an exclusion of the disease on its absence, provided sufficient time have elapsed for inflammatory exudation, and limiting the question of diagnosis to the first stage. The murmur is almost pathognomonic taken in connection with the symptoms and history; yet there is one source of fallacy—namely, the production of an intrapleural friction murmur by the movements of the heart in cases of pleuritis. A friction murmur accompanying the systolic and diastolic movements of the heart, continuing while the patient's breathing is voluntarily suspended, may be thus produced irrespective of pericarditis. I have met with several examples, the absence of pericarditis, notwithstanding a well-marked murmur with cardiac rhythm, having been determined by examination after death. This is called a *cardiac-pleural friction murmur*, and has been already alluded to under the head of Diagnosis of Acute Pleuritis. It is to be suspected, if pleuritis be known to exist with or without pneumonia; when the murmur is limited to the border of the heart, the intensity of the murmur varying much more than the ordinary cardiac murmur during the periods of examination, it being heard in some cases only at the end of inspiration, and generally being affected more or less by the respiratory movements.

In the second stage the occurrence of liquid effusion and its amount are determined by percussion. Abnormal dulness or flatness exists over an increased area in the præcordial region. The pericardial sac, if filled with liquid, forms a pyriform tumor, the boundaries of which are readily defined by percussion. The base is situated below the level of the apex-beat in health; the left border extends beyond the left nipple to a greater or less extent, and the right border between the right margin of the sternum and the right nipple; the apex is near the sternal notch. The situation, size, and shape of the area of dulness or flatness point to pericardial effusion. If the pericardial sac be partially filled with liquid, the area of dulness in the præcordia is abnormally widened at and below the apex of the heart, the widening extending more or less upward in proportion to the quantity of effusion. Vocal resonance is diminished or absent within the area of dulness or flatness, and also vocal fremitus. If the sac be distended with liquid, the præcordia may be abnormally prominent and the intercostal depressions abolished, as in pleuritis, within this region. Mensuration will show the increased size of the præcordia. The extent of dulness or flatness at different periods of the disease will show, on the one hand, progressive increase, or, on the other hand, diminution of the quantity of liquid, and at length its complete removal. Dr. J. M. Rotch has called attention to the fact that the pericard-

sac, when filled, gives rise to flatness on percussion in the fifth intercostal space on the right side—a fact which I have clinically verified.

The friction murmur either diminishes or disappears after considerable effusion of liquid has taken place. Not infrequently it continues, although the pericardial sac may be filled with liquid and even much dilated. Under these circumstances it is sometimes heard when the patient is raised to the sitting posture, and it may disappear when the patient lies on the back. If it have disappeared or been diminished during the stage of effusion, it returns with increased intensity after the absorption of the liquid, and it then persists until agglutination of the pericardial surfaces takes place. Occasionally it continues during convalescence and after apparent recovery.

The apex-beat of the heart is weakened and may be suppressed by the presence of liquid. If the accumulation of liquid be considerable, the situation of the beat is altered. It is raised to the fourth intercostal space, and carried to the left as far as, or even beyond, the line of the nipple. The sounds of the heart are rendered feeble and distant by the presence of liquid, especially the first sound, and this becomes short and valvular like the second sound.

By means of these signs the diagnosis of pericarditis is generally made without difficulty. Bearing in mind the frequency of its occurrence in articular rheumatism, daily examinations of the chest in cases of that disease with reference to this complication should not be omitted. The fact that it occurs in cases of Bright's disease should also be borne in mind; in fact, it is a good rule, in examining a patient with any disease, not to omit an exploration of the præcordia. Developed in connection with pleuritis or pneumonitis, it may be overlooked, and the diagnosis involves more difficulty than when it occurs in other pathological connections. The determination of pericardial effusion, if a large effusion also exist in the left pleural sac, is not always easy, and the chief reliance in such a case must be on the presence of a friction murmur, which is produced, not without, but within, the pericardial sac. [Even when large pericardial effusion is uncomplicated with pleural effusion its diagnosis is by no means easy. It is very apt to be mistaken for an accumulation of fluid in the pleural sac. Dr. Fagge states that "all the examples of very large pericardial effusion which have occurred at Guy's Hospital have been set down to pleurisy."—H.] I have reported a case in which the heart was enveloped in either a carcinomatous or sarcomatous growth, completely filling and distending the pericardial sac without altering its form.¹ In this unique case the signs were those of pericardial effusion, and this was the diagnosis. It is difficult to see how pericardial effusion could be excluded in such a case, except by means of an exploratory puncture, which might have been resorted to without harm.

In a case under my observation the pericardium became agglutinated over the left half of the heart, and the right half of the sac was filled with effused liquid. Such a case, if not observed from the beginning, offers a puzzling problem in diagnosis.

The occurrence of delirium, coma, etc. in some cases of pericarditis masks the symptoms pointing to the latter. An examination for the signs of pericarditis should not be omitted in cases presenting notable disturbance of the nervous system.

PROGNOSIS.—Acute pericarditis is in some cases a very dangerous disease, but in other cases comparatively mild. The gravity depends much on the intensity of the inflammation, the amount of inflammatory exudation, and more especially the quantity of liquid effusion, together with the rapidity with which it takes place. A large quantity of liquid, rapidly effused, may lead

¹ Vide *Treatise on Diseases of the Heart*, 2d ed.

quickly to a fatal termination. Death in such cases is caused by paralysis of the heart from compression, and cases have occurred in which life was destroyed in this way after the lapse of a few hours only from the time of the attack. Generally, however, the duration of the disease in fatal cases is from one to two weeks, and death takes place by slow asthenia. In such cases the immediate cause of death is either the prolonged compression of the heart by liquid, or weakening of the heart's action as a direct effect of the inflammation on the muscular fibres, or both causes combined. Sudden death by syncope is liable to be produced by muscular exertion, especially if there be much liquid effusion. A patient under my observation, affected with mild pericarditis, died instantly on getting out of bed to go to stool.

The fatality in cases of acute pericarditis is often due, not so much to the disease *per se*, as to coexisting affections. In fact, exclusive of the accidents just referred to, the disease tends to recovery. The danger varies greatly with its different pathological connections. Rheumatic pericarditis, not associated with pleuritis or pneumonitis, is rarely fatal. On the other hand, pericarditis developed in the course of Bright's disease proves fatal in a very large proportion of cases. This difference is explained by the ability of the system to sustain any important intercurrent affection being widely different in these two diseases. Cases in which the pericarditis occurs as a complication of pleuritis or pneumonitis show a large fatality. Traumatic cases generally end in recovery, provided the heart be not injured. Occurring as an idiopathic affection and uncomplicated, the prognosis is favorable.

If the disease do not prove fatal during its acute course, it either ends in recovery or it becomes chronic. Chronic pericarditis will claim separate consideration. In the cases which end in recovery the usual result is adhesion, by the intervention of newly-formed tissue, of the pericardial surfaces over the whole or the greater part of the organ. In a small proportion of cases the adhesion is limited to a few small spaces. Occasionally, patches of fibrous tissue, without adhesion of the two surfaces, are the only permanent effects of the disease. It is doubtful if complete absorption of the inflammatory exudation ever takes place, followed by no adventitious tissue and leaving no trace of the disease.

TREATMENT.—The widely different circumstances under which acute pericarditis occurs must of course be taken into account in the treatment. The question as to the propriety of bloodletting and other measures heretofore distinguished as antiphlogistic can only be entertained in the first stage of the disease and when it is idiopathic or traumatic or connected with rheumatism. These measures are undoubtedly inappropriate when it is developed in the progress of Bright's disease or when it is secondary to pleuritis or pneumonitis. In general terms, the propriety of these measures admits of consideration only when the pericarditis is either primary, or secondary to affections which do not in themselves impair considerably the ability of the system to sustain an additional disease. When not associated with other diseases which are in themselves dangerous, it is to be borne in mind that pericarditis tends to recovery.

In the cases to which bloodletting must be limited the general principles which are to govern its employment are the same as in other acute inflammations. These principles have been considered.¹ Some importance, perhaps, belongs to this consideration—namely, by diminishing the mass of blood the heart is less excited and its labor diminished. On the other hand, it is to be considered that the danger incident to the disease is mainly from paralysis of the heart or impairment of its muscular power. Giving due weight to these considerations, bloodletting should be employed with great circumspection.

¹ Vide p. 33 *et seq.*

even in the few cases in which the symptoms relating to the circulation, in the first stage of the disease, may appear to indicate it. It is never indicated after considerable effusion has taken place. [The safest and perhaps the most effective method of depletion is by leeches, of which from six to twelve or more may be applied to the præcordial region.—H.]

Depletion by means of saline purgatives is indicated, in the first stage, by the same symptoms as in other acute inflammations. This remark is alike applicable to nauseant and other sedatives. These should be limited to the first stage. They might prove pernicious if continued after effusion has occurred, and hence the great importance of determining the presence of liquid and its amount by physical signs.

Shall the system be brought under the influence of mercury in the first stage? This is a question which different writers and practitioners have answered differently, some advocating rapid mercurialization as highly important, others regarding it as needless and hurtful. In the cases in which mercury is by some considered important, and by many admissible, my experience leads me to be satisfied to forego its use.

Opium is of great value in this as in other acute inflammations. It is indicated by pain and constitutional disturbance, and is to be employed sufficiently to relieve the general and local symptoms. The form of opiate and the mode of administration are to be determined by the circumstances in individual cases.

Locally, mild revulsive and soothing applications are useful in the first stage. Sinapisms, a poultice, the water-dressing, or the spongio-piline saturated with a warm anodyne infusion may be employed. Blisters in this stage should not be employed. Aside from their interference with the daily physical explorations, which are vastly important, they do more harm by adding to the pain and constitutional disturbance than good by way of revulsion. By German writers cold applied to the præcordia, as in the treatment of acute pleuritis and pneumonitis, is said to be useful. The evidence of its usefulness is the relief of pain, together with diminished frequency of the heart's action.

The indications in the second stage relate, *first*, to the liquid effusion. If the amount of effusion be sufficient to enfeeble the heart by compression, it is highly important to effect the removal of the liquid as speedily as possible. For this end the præcordia may be painted daily with the tincture of iodine, or small blisters may be applied, removing them as soon as vesication begins, and allowing the blistered surface to dry up rapidly. Hydragogue cathartics and diuretics may be employed, as in pleuritis, taking care not to carry these measures so far as to depress the vital powers and weaken the heart's action. This caution is of great importance, and it suggests a *second* indication which may be present in the second stage—namely, to strengthen the heart's action and support the powers of life by the timely and judicious use of alcoholics, tonics, and nourishment. Keeping in view the fact that the disease, if it end fatally, destroys life by affecting directly the heart's action, the measures just named are indicated with an urgency proportionate to the degree of feebleness of the circulation. All measures which tend directly or indirectly to weaken the circulation or depress the vital powers are contraindicated in the second stage. The liability to fatal syncope on exertion is to be borne in mind, and quietude should be rigidly enjoined. Feebleness and irregularity of the pulse in the second (and sometimes in the first) stage constitute an indication for digitalis, which, however, should not be given sufficiently to retard unduly the heart's action.

During the stage of convalescence precautions against undue excitement of the action of the heart by exercise, mental emotions, over-repletion of the

stomach, etc. are more important than during recovery from most other acute inflammations. At the same time, convalescence will be expedited and complete recovery secured by a nutritious diet, tonic remedies, gentle gestation out of doors, and other hygienic measures to promote speedy recuperation.

In the treatment of pericarditis developed in the course of either rheumatism or renal disease it may be important to take into account the supposed presence in the blood of a morbid material upon which the pericardial inflammation depends. The indication derived from this view of the causation is, in general terms, to remove, if possible, the continued operation of the cause by measures addressed to the morbid conditions of the blood belonging to those affections. This part of the treatment, however, will be more appropriately considered hereafter in connection with rheumatism and renal disease. The importance of measures to prevent the development of pericarditis in the course of these diseases will also be then considered.

If the disease end in recovery without becoming chronic, adhesion of the pericardial surfaces to a greater or less extent may be expected to take place. This result was formerly supposed to lead to progressive enlargement of the heart, and therefore pericarditis was regarded as a highly serious disease with reference to its remote effects. This is an error which arose from imputing to pericardial adhesions the consequences of the valvular lesions which often coexist. It may be doubted if adhesions alone tend to produce enlargement, and there is reason to believe that if not associated with valvular lesions they may give rise to little inconvenience. The pericardial surfaces are not infrequently found, in autopsical examinations, universally adherent as a result of ancient pericarditis, without any other evidence of cardiac disease, when no symptoms referable to the heart had existed during life. Universal adhesions may be diagnosticated by finding the apex of the heart immovable when the body is placed in different positions; by a visible retraction of the chest-wall and epigastrium synchronously with the ventricular systole; and by the superficial cardiac space remaining unchanged by a deep inspiration. These physical signs denote adhesions not only of the visceral and parietal surfaces of the pericardium, but of the external surface to the adjacent lung and the parietes of the chest. If the latter adhesions have not taken place, the data for a diagnosis are wanting.

Chronic Pericarditis.

Chronic pericarditis may be subacute from the beginning, or it may follow the acute form of the disease. If acute pericarditis do not end in convalescence after the lapse of from two to three weeks, it becomes a chronic affection. As regards anatomical characters, cases differ. In some cases of chronic pericarditis there is no liquid effusion, but the pericardial surfaces are agglutinated by several layers of fibrinous exudation, which collectively may be half an inch or more in thickness. Under these circumstances the exudation is not absorbed, a low grade of inflammation continues, and the disease often ends fatally after a variable duration.

In other cases liquid effusion remains and progressively accumulates; the pericardial sac becomes more or less dilated, and it is sometimes so much enlarged as to depress the diaphragm and occupy the greater part of the thoracic space. In a case reported by Dr. T. P. Satterthwaite the liquid removed after death amounted to eight pounds and four ounces.¹ In a case reported by the late Dr. Swett the quantity of liquid was at least a gallon.

¹ *Richmond and Louisville Med. Journal*, April, 1872.

In chronic pericarditis without liquid effusion pain is rarely prominent. The symptoms are those dependent on feebleness of the circulation due to the impaired muscular power of the heart, and on constitutional irritation. In the cases in which large effusion exists the heart is weakened by compression, and the patient suffers from dyspnoea caused by interference with the respiratory function. The dyspnoea may amount to orthopnoea if the accumulation of liquid be large. Pain under these circumstances is rarely a prominent symptom. The symptoms mentioned as due to the pressure of the pericardial sac filled with liquid in the second stage of acute pericarditis may be still more marked when the sac is dilated by effusion in the chronic form of the disease. These symptoms are—aphonia, from pressure on the recurrent laryngeal nerves; dysphagia, from pressure on the oesophagus; cyanosis and turgescence of the cervical veins, from pressure on the venae cavæ and the yielding walls of the auricles; and singultus, from pressure on the phrenic nerve or branches of the par vagum.

Chronic pericarditis with effusion is not to be confounded with pericardial dropsy (hydro-pericardium). The latter occurs in connection with general dropsy, and the accumulation of serum is rarely, if ever, sufficient to dilate the sac. In chronic as in acute pericarditis the liquid is generally sero-fibrinous. In rare instances it is purulent (pyo-pericardium). The effused serum is sometimes colored with blood. This variety of pericarditis, called hemorrhagic, does not claim separate consideration. The term hæmo-pericardium denotes the presence of blood either with or without pericarditis. Without pericarditis it may be a consequence of wounds which penetrate the pericardial sac, and of the rupture of either the heart or an aneurism. In most, if not all, cases of so-called hemorrhagic pericarditis the liquid is bloody serum. This occurs especially in pericarditis associated with purpura hæmorrhagica and scorbutus.

The DIAGNOSIS, if liquid effusion be not present, must often be inferential, being based mainly on the knowledge of the existence of antecedent acute pericarditis. Creaking friction murmur exists in some cases, notwithstanding the agglutination of the pericardial surfaces. If friction murmur be not present and acute pericarditis be not known to have existed, a positive diagnosis is extremely difficult, if not impossible. The heart is found to be more or less enlarged, but there are no means of determining that the enlargement proceeds from a deposit of fibrin. If liquid effusion be present the physical signs render the diagnosis easy and positive. Flatness on percussion exists on the anterior surface of the chest, extending on either side of the sternum toward the axillary region in proportion as the pericardial sac is dilated. Obliteration of the intercostal depressions, and even bulging, may be observed. In a young subject there may be notable projection of the præcordia. Fluctuation in the intercostal spaces is sometimes felt. Laterally, beyond the limit of the flatness on each side, resonance on percussion and the respiratory murmur show the presence of lung. The heart's impulse is suppressed, but a shock communicated by the action of the heart may be felt. A friction murmur is sometimes heard, even when the quantity of effused liquid is very large. The sounds of the heart are feeble, the first sound being distant, more weakened than the second, and short and valvular like the second sound. These signs render the diagnosis sufficiently clear.

The PROGNOSIS in cases of chronic pericarditis is always extremely unfavorable. The disease ends fatally after a duration varying much in different cases.

The indications for TREATMENT are to improve the tone of the system and impart vigor to the heart by tonic remedies, together with nutritious diet and other hygienic measures. The propriety of much counter-irritation is doubt-

ful. Everything which tends, directly or indirectly, to weaken the heart or the vital powers is to be avoided. In this point of view mercurialization is objectionable. If there be much liquid effusion, diuretic remedies and small blisters may be tried. Hydragogue cathartics in these cases, if the patient be feeble, are to be employed with great circumspection. In a case under my observation elaterium, given in small doses and producing but a moderate effect, appeared to hasten the fatal termination. Iodine may be employed as a sorbefacient, externally and internally.

The question as to the propriety of paracentesis relates chiefly to cases of chronic pericarditis. Instances, however, may occur in which, owing to a rapid and large effusion of liquid, this question may arise in connection with the acute disease. If life be in immediate danger from the quantity of liquid, whether the inflammation be acute or not, there can be no room for doubt concerning the propriety of withdrawing the liquid by aspiration; but this question is not restricted to the cases in which it is indicated to avert impending death. May not the rules of practice now generally accepted in cases of pleuritis with effusion and empyema be applied to similar conditions in cases of pericarditis? From a rational standpoint the answer is affirmative. Following these rules, if a large accumulation of liquid remain undiminished by other measures of treatment continued for a reasonable period, aspiration should be employed, and the latter is always indicated in suppurative pericarditis.

As preliminary to the operation there is apparently no objection to an exploratory puncture in order to demonstrate the presence of liquid and to ascertain its character. No harm can arise from the puncture with a needle attached to a hypodermic syringe. Even should the heart be punctured therewith, no serious consequences would follow. A needle, however, should not be used in aspiration, except for the objects just stated. A small-sized trocar is unobjectionable. The suction force by means of Davidson's syringe, properly adapted, is preferable to that produced by Dieulafoy's apparatus or its modifications, the former being simpler and more easily managed.

Roberts has tabulated 60 cases of paracentesis of the pericardium. Of these cases, the number of recoveries was 24. Of the fatal cases (36), 23 survived the operation for one day or longer, the average duration of life being over twenty-seven days, and the longest duration one hundred and sixty days.¹ These results strongly sustain the propriety of the operation, especially when it is considered in how large a proportion of cases pericarditis is associated with other grave affections, and that up to the present time the operation has generally been *en dernier ressort*.

The most eligible point for making the puncture is the fifth intercostal space between the sternum and the linea mammillaris, somewhat nearer to the former than to the latter. It is probably an important precaution to withdraw the liquid very slowly. If the liquid be purulent, and, after repeated aspirations, pus continue to reaccumulate, it is very evident that a permanent opening into the pericardial cavity affords the only hope of effecting a cure.

Pneumo-Pericarditis.

This name denotes the presence of air or gas within the pericardial sac in cases of pericarditis. Air or gas may find its way into this situation through a wound of the thoracic walls or of the œsophagus, and through a fistulous communication between the lungs or the stomach and the pericardial cavity. Air may get access into this cavity through a wound of the chest, and peri-

¹ *Paracentesis of the Pericardium*, by John B. Roberts, A. M., M. D., etc., 1880.

carditis not be developed. The condition then is expressed by the term *pneumo-pericardium*. I have reported a case exemplifying this statement.¹

The presence of air and liquid gives rise to splashing and sometimes metallic sounds with the movements of the heart, which are heard on auscultation. Percussion over the præcordia elicits a tympanitic resonance. These cases belong among the curiosities of clinical experience. The treatment of pneumo-pericarditis involves the same principles as the treatment of pericarditis without the presence of air or gas.

[One of the most interesting of the few recorded cases of pneumo-pericarditis was reported by the late Dr. J. F. Meigs of Philadelphia, under the title of "pneumo-hydropericarditis."² The patient was a young man æt. 18, who shortly before death exhibited in perfection the signs of this rare condition. Chief among them was a splashing or churning sound synchronous with the heart's action and audible at a distance of several feet from the patient. In addition, the heart-sounds were amphoric or metallic, and there were the friction-sounds, also metallic in character, of the coincident pericarditis. In this case the air was admitted into the pericardial sac through an ulcerated opening in the œsophagus, this fact having only been ascertained after the most careful dissection.—H.]

Of 28 cases collected by Müller,³ 9 terminated in recovery. The cases due to traumatism offered the most favorable prognosis. Of 14 such cases, 6 recovered.

CHAPTER II.

ENDOCARDITIS.—MYOCARDITIS.—DISEASES OF THE CORONARY ARTERIES.

Simple Endocarditis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Acute Ulcerative Endocarditis.—**Myocarditis.**

INFLAMMATION of the membrane lining the cavities of the heart, or the endocardium, is called endocarditis.

The inner surface of the endocardium is lined by a single layer of flat, polygonal endothelial cells. Beneath this is a layer of connective tissue extremely rich in elastic fibres. This elastic layer, which with the endothelium constitutes the endocardium, is connected with the muscular wall of the heart by a layer of ordinary fibrillated connective tissue in which may be found scattered muscular fibres. Blood-vessels are present in this layer, but the endocardium itself is non-vascular. The valves may be regarded as duplicatures of the endocardium, between the lamellæ of which is a strengthening layer of fibrous tissue derived from the fibrous rings of the ostia. The semilunar valves are devoid of blood-vessels, and the auriculo-ventricular valves usually contain only a few blood-vessels near their attached borders (Langer). Inflammation of the valves often leads to a new formation of blood-vessels in their substance.

¹Vide *Practical Treatise on Diseases of the Heart*, 2d ed.

²*Am. Journ. Med. Sci.*, Jan., 1875.

³Müller, "Drei Fälle von Pneumopericardie," *Deutsches Archiv für klinische Medicin*, Bd. 24, S. 158, 1879.

The inflammatory lesions of the valves of the heart are most frequently situated, not upon the free edge of the valve, but upon a thickened line a short distance from this edge, known as the line of closure of the valves.

The inflammations of the endocardium may be divided into simple endocarditis, which may be acute, subacute, or chronic, and acute ulcerative, or malignant endocarditis.

Simple Endocarditis.

A sharp line cannot be drawn between the acute and the chronic manifestations of this disease. A subdivision into verrucous or papillary endocarditis in which the anatomical lesions appear as warty excrescences on the endocardium, and sclerotic or contracting endocarditis, in which the valves become thickened and shrunken, has been made, but these two varieties of lesions are so intimately related to each other, and so frequently combined, that they will be considered under a common heading.

ANATOMICAL CHARACTERS.—Endocardial inflammation, in the great majority of cases, is situated on the valves and chordæ tendineæ. It is relatively infrequent on the endocardium lining the cavities of the heart. After birth it is generally limited to the left side of the heart. In the rare cases of endocarditis of the right side after birth the left is likewise generally involved. Before birth endocarditis of the right ventricle is most common. Fœtal endocarditis has been often observed, and in the vast majority of cases it is confined to the right side.

Redness, which plays such an important part in the anatomical appearances of the early stage of acute inflammations in most situations, is not of much importance in endocarditis. A diffuse reddish staining of the endocardium, due to post-mortem imbibition of dissolved blood-coloring matter, must not be mistaken for inflammatory hyperæmia. Nothing is known as to the existence of inflammatory exudation upon the free surface of the endocardium. The essential anatomical characteristic of endocarditis, especially in its early manifestations, is the appearance of so-called vegetations upon the endocardium. These vegetations may be minute and in great number, giving only a roughened appearance to the affected endocardium, or they may attain the size of a pea or be even larger. They are of all shapes, and may be connected with the tissue of the endocardium by a broad base or by a narrow pedicle. They cannot be removed from the endocardium without leaving a loss of substance. This fact, together with their microscopical examination, shows that they are outgrowths from the tissue of the endocardium, and not merely fibrinous deposits from the blood, as was once supposed. They are formed by a nodular accumulation of young cells, partly emigrated white blood-corpuscles and partly young connective-tissue cells, in the upper connective-tissue layer of the endocardium. They constitute a kind of granulation-tissue over which the endothelium has disappeared. New blood-vessels are frequently found in these vegetations. A more diffuse infiltration with leucocytes, especially around the vegetations, is also met with in the endocardium. Upon the roughened surface of the vegetations white thrombi are deposited from the blood. These thrombi, which may be of considerable thickness, are formed chiefly of blood-plates, white blood-corpuscles, and fibrin. The vegetations, with their caps of fibrin, are favorable points for the detachment of emboli, which may consist either of broken-off thrombi or of fragments of the vegetations. Less frequently than in acute ulcerative endocarditis, loss of substance of the endocardium may occur from breaking off of the vegetations or by necrosis and fatty disintegration of the surrounding infil-

trated endocardial tissue. Thus, there may result perforation of the valves, or, on the other hand, valvular aneurism in consequence of bulging of their thinned and softened coats.

In the subacute and chronic forms of endocarditis the vegetations are firmer in their texture, and do not consist so much of granulation-tissue as of fibrillated connective tissue. These firm vegetations may be developed out of the soft, acute vegetations, or they may have been slow in their growth from the beginning. The valves are also much deformed by the thickening of their substance in consequence of the development of new connective tissue, which shrinks and causes retraction of the curtains. At the same time, the chordæ tendineæ are often shrunk and thickened. Abnormal adhesions between the edges of the valves or between the valves and the heart-wall are frequently formed. Regressive metamorphoses, in the form of necrotic foci, of fatty degeneration, and of calcification of the vegetations and of the thickened endocardium, are usually observed. These various changes in acute and chronic endocarditis lead to the development of valvular stenosis and insufficiency.

CLINICAL HISTORY.—Authenticated cases of endocarditis disconnected from other diseases, which serve to mask its symptoms to a greater or less extent, are wanting. The clinical history of the disease, therefore, as far as it is at present known, will require but a brief space. Our knowledge of the disease is confined chiefly to the cases in which it occurs in connection with acute articular rheumatism, and in a certain proportion of these cases it is associated with pericarditis. Pain referable to the præcordia is rarely, if ever, a prominent symptom. The patient may complain of an obscure sense of distress in the præcordia, not amounting to pain. The action of the heart may be morbidly excited. The organ beats with abnormal quickness and frequency, and its action may be irregular. The action of the heart may be out of proportion to the force of the pulse. The local symptoms, in short, as regards the action of the heart, are those of palpitation. In proportion to the acuteness of the inflammation, doubtless febrile movement is induced, together with the symptoms of constitutional disturbance which accompany fever symptomatic of inflammation in other situations. The local and general symptoms, however, are often not prominent, and as far as these are concerned the disease is not infrequently latent. Hence the existence of the disease was unknown prior to the early part of the present century.

PATHOLOGICAL CHARACTER.—The morbid changes which belong to simple endocarditis are in many respects the same as in serous inflammations. Inflammatory products on the surface of the membrane, if they occur in this situation, are carried by the blood-current into the circulation. The local effects of the endocardial inflammation are warty growths, fibrinous deposits, adhesions, etc., an account of which has been given under the heading Anatomical Characters.

CAUSATION.—Endocarditis, in the great majority of cases, is not a primary disease. There is reason, however, to believe that it occurs not very infrequently, and is overlooked in consequence of its latency as regards cardiac symptoms. This may be inferred from the number of cases in which valvular lesions referable to inflammation are found in persons who have never had the disease in the course of which endocarditis is likely to be developed—namely, articular rheumatism. As recognized in practice, it is generally incidental to the disease just named. The proportion of cases of rheumatism in which it occurs is not settled. The statistics of different observers show a variation of from $\frac{1}{3}$ to 9 per cent. A reason for this variation is that the existence of

the disease has been often assumed on insufficient evidence. The ground for this statement will appear in connection with the consideration of the diagnosis. The analysis by Sibson of 325 cases of acute rheumatism, observed by him, gave 79 cases in which there was no evidence of endocarditis; in 161 cases the evidence of endocarditis was considered as positive; it probably existed in 13 cases, and it was noted as threatened in 63 cases. It is probable that in some cases the evidence was considered as complete on insufficient grounds. This statement will apply to cases in which the only evidence was a tricuspid regurgitant murmur or an aortic direct murmur, and to cases in which valvular lesions may have existed prior to the rheumatism. The cases of probable and threatened endocarditis cannot be said to have any statistical value. The frequency of rheumatic endocarditis is doubtless affected in not a small degree by the treatment adopted in the early period of rheumatism. It suffices to say that endocarditis occurs frequently in cases of rheumatism. Endocarditis, like pericarditis, may perhaps in some cases precede the affection of the joints. It may occur at any time in the course of a rheumatic attack, but it is usually developed in the early or middle period.

When developed in the course of rheumatism, it is not from the transference of the affection of the joints to the endocardial membrane—that is, by a metastasis—but, like pericarditis developed in the same connection, it is produced by the causative condition which gives rise to the articular affection.

Endocarditis and pericarditis are not infrequently associated in cases of rheumatism, and this compound affection is called *endo-pericarditis*. Rheumatic pericarditis rarely exists without endocarditis. The reverse of this, however, does not hold good: endocarditis is not infrequently developed without pericarditis. In Sibson's cases endocarditis without pericarditis occurred in 107, and endo-pericarditis existed in 54.

Endocarditis, either with or without pericarditis, is developed, in a certain proportion of cases, in the course of Bright's disease. It occurs occasionally in the eruptive and continued fevers and in cases of pyæmia. It may possibly be produced by contusions of the chest. Its occurrence in chorea is supposed to be frequent. Evidence of its existence was regarded as sufficient in 13 of 34 cases observed by Sibson. The sufficiency of the evidence, however, in all of the 13 cases admits of doubt. This frequency of its occurrence is consistent with the supposed relationship of chorea to rheumatism. Recurring attacks of endocardial inflammation not infrequently take place in connection with existing valvular lesions of the heart.

[The opinion is gaining ground that simple endocarditis, like the ulcerative form of the disease, is due to the agency of micro-organisms, although search for the latter often yields negative results. The results of bacteriological research favor the view that the streptococcus pyogenes is most frequently associated with ulcerative endocarditis, while the staphylococcus pyogenes aureus is most commonly present in cases of simple endocarditis.—H

DIAGNOSIS.—The symptoms in cases of endocarditis are insufficient for positive diagnosis. The symptoms are even less diagnostic than those which belong to the clinical history of pericarditis, and the disease is oftener completely latent. The diagnosis of this disease, as well as of pericarditis, must rest on physical evidence. The vegetations and fibrinous deposits give rise to an endocardial murmur, and the diagnosis is to be based on the development of this murmur, taken in connection with the symptoms. As the anatomical changes are situated especially upon the curtains of the mitral valve, at least in cases of rheumatic endocarditis, the murmur is usually of mitral origin. The murmur is of a soft or bellows character. It accompanies the

first sound of the heart; that is, it is systolic. It is heard loudest at or near the apex of the heart, and may be limited to this situation. As a rule, if prior to the endocarditis the patient were free from valvular lesions, the systolic murmur is not propagated far without the left border of the heart. The anatomical changes which occur during the progress of simple endocarditis do not involve immediate valvular insufficiency either at the mitral or aortic orifice. Hence, the mitral murmur does not proceed from an actual regurgitant current from the ventricle to the auricle. It is not, then, correct to call it a mitral regurgitant murmur. It is an intraventricular murmur, or it may be called a *mitral systolic murmur*, this term not implying the occurrence of regurgitation.

Positive evidence of endocarditis is not afforded by the existence of the murmur just named. A mitral murmur exists often without denoting existing inflammation. It may proceed from valvular lesions which are to be presently considered. To be evidence of existing endocarditis, the murmur must be developed under observation; in other words, one must be satisfied that the murmur which is discovered did not exist on a previous examination. As it is in cases of rheumatism especially that endocarditis occurs, let it be assumed that on the first examination of a patient affected with rheumatism a mitral murmur is found. The murmur is not proof of endocarditis, for it is not known that the murmur did not exist prior to the rheumatic attack. The existence of endocarditis is only probable, and the probability of the disease is greater if this be the first attack of rheumatism. But if, on a first examination, no murmur be found, and subsequently a mitral murmur become developed, it is evidence of endocarditis. The evidence is strengthened if at the same time præcordial distress and excited action of the heart point to the occurrence of a cardiac complication.

Reference has been made, thus far, to a mitral murmur only as evidence of endocarditis. Vegetations and fibrinous deposits at the aortic orifice may occur in this disease, giving rise to an aortic murmur. An aortic direct murmur, and also a pulmonic direct murmur, however, are not infrequent in cases of rheumatism without endocarditis, more especially in women, being due to the condition of the blood; in other words, being inorganic murmurs. Hence, a positive diagnosis of endocarditis is not to be based on these murmurs, unless the symptoms at the same time denote a cardiac complication and pericarditis is excluded. Irrespective of cases of rheumatism, it is well known that an aortic murmur with the first sound—*i. e.* systolic—is common as an inorganic murmur, and alone is never proof of endocarditis. Insufficiency of the aortic valve as an immediate effect of endocarditis must be rare. Sibson, however, gives some instances in which this effect was shown by the occurrence of an aortic regurgitant murmur developed during the rheumatism, and afterward disappearing.

Endocardial murmurs produced by endocarditis may or may not remain permanently. I have repeatedly known a mitral murmur to disappear after recovery from rheumatism. I have known an aortic and a mitral murmur to continue for several years after recovery, and at length to disappear entirely. In cases of endo-pericarditis the endocardial exists with an *exocardial* or friction murmur. In general, the two murmurs may be readily distinguished, and each referred to its source.

PROGNOSIS.—In the great majority of cases simple endocarditis involves no immediate danger. The danger is for the most part remote, relating to the valvular lesions which often follow. (Vide Chapter III.) The persistence of inflammation in a chronic form is not determinable. The continuance of an endocardial murmur is not proof that inflammation persists;

and roughening of the membrane from either vegetations or thrombi which remain will suffice to produce a murmur. The chief source of important morbid effects, exclusive of valvular lesions, is embolism. Vegetations or masses of fibrin of greater or less size are liable to be detached, and, forming emboli, occasion obstruction of arteries in different organs. Passing, of course, into the systemic circulation, they are most likely to become lodged in the spleen and in the kidney, where they give rise to infarctions. They may be carried into the central artery of the retina and give rise to impairment of vision. Again, cerebral embolism may occur, and there have been cases in which gangrene of the lower limbs has resulted from embolic obstruction of their distributing arteries. In the latter case the arteries are generally atheromatous or the circulation is much enfeebled. These are accidents incident to endocarditis. In general, as occurring in its usual pathological connection—namely, in the course of acute articular rheumatism—and disconnected from pericarditis, endocarditis involves no immediate danger and gives rise to no symptoms denoting gravity of disease; but it is frequently latent, and is an important complication, chiefly because it may be the foundation for valvular lesions which, after the lapse of many months, or it may be many years, occasion serious consequences.

TREATMENT.—Simple endocarditis, being confined, generally, to the left side of the heart, and limited chiefly to the valvular portion of the endocardium, does not occasion great constitutional disturbance. Præcordial pain and disturbed action of the heart indicate anodyne remedies and soothing applications to the chest. Blisters with reference to these symptoms are of doubtful propriety. Sinapisms and stimulating liniments will secure all the advantages to be derived from counter-irritation.

Measures addressed to the supposed causative condition of the blood are rationally indicated. Occurring generally in connection with rheumatism, if the local manifestations, this affection of course included, depend on the presence of a morbid material in the blood, it is plainly an object either to neutralize or eliminate this material. The means to be employed for this object will be hereafter considered in connection with the subject of rheumatism; but it may be here stated that the most important measure is the administration of alkaline remedies in doses sufficient to produce and maintain alkalinity of the urine. The importance of this measure in order to prevent the occurrence of both endocarditis and pericarditis in cases of rheumatism will enter into the consideration of the treatment of the latter disease.

The remote evil consequences of endocarditis proceed from thickening, morbid growths, and the deposit of fibrin upon the valvular portion of the endocardium. It is therefore undoubtedly desirable to limit and remove these immediate effects of the inflammation. The condition of hyperinosis is more marked in rheumatism than in any other disease, and perhaps increases the tendency to fibrinous deposits. With this view, measures addressed to that condition are rationally indicated. Alkaline remedies, there is reason to believe, lessen the liability to fibrinous deposits. Mercury has been supposed to have this effect. That it possesses this power, however, has been inferred rather than demonstrated, and the correctness of the inference admits of doubt. It may be doubted whether the fibrin deposited upon the membrane be ever absorbed; it either remains or is washed away, gradually or in mass, by the current of blood. The importance of absolute rest during the endocardial inflammation and for some time afterward has been enjoined by Sibson, and more especially by Fothergill.¹ The object is to secure a normal minimum of the heart's action in order to prevent changes

¹ *The Heart and its Diseases*, by J. Milner Fothergill, M. D., etc., 2d ed., 1879.

in the valves leading to permanent valvular lesions. It is reasonable to suppose that these are promoted by an increased strain upon the valves weakened by existing or recent inflammation; hence, everything is to be avoided which will increase the strain beyond that necessarily involved in the tranquil action of the heart. This precaution embraces avoidance of not only physical exertion, but also mental excitement, a stimulating diet, and the use of alcoholics. It is to be added, however, that a good nutrition is to a certain extent protection against these lesions. A diet so reduced as to occasion impoverished blood is injurious.

The practitioner should bear in mind that the persistence of an endocardial murmur is not sufficient ground for persistent medication. The persistence of the murmur is not evidence that the inflammation continues. The medicinal treatment of endocarditis should cease when the local and general symptoms of the disease are no longer present.

Acute Ulcerative Endocarditis.

Among the synonyms for this affection may be mentioned diphtheritic, mycotic or bacteritic, malignant, puerperal, septic, and pyæmic endocarditis. The name acute ulcerative endocarditis is perhaps not the best, as simple endocarditis may be attended with the formation of ulcers, but it is the name commonly employed.

Acute ulcerative endocarditis is distinguished by the malignancy of its course. It may be primary, but it is usually secondary to acute infectious diseases, and in either case it is accompanied by symptoms of severe blood-poisoning, and usually by the development of multiple abscesses. Acute ulcerative endocarditis is due to infection with bacteria, which are always to be found in the valvular lesions.

ANATOMICAL CHARACTERS.—The endocardium presents, in this disease, little necrotic patches of an opaque, yellowish-white appearance. By the breaking down and separation of these patches of dead tissue ulcers are formed. Both the ulcers and the patches of necrosis are usually covered by reddish-gray, soft thrombi, composed of bacteria, blood-plates, leucocytes, fibrin, and red blood-corpuscles. In the margins of the ulcers, and around and subsequently within the necrotic foci, are accumulated small, round cells, probably emigrated white blood-corpuscles. The substance of the affected valves to a greater or less extent is swollen, softened, and lustreless.¹

Valvular aneurisms may be formed by bulging out of the thinned and softened endocardium at the base of the ulcers in consequence of the pressure of blood. These aneurisms, when on the mitral valve, project toward the auricle; when on the aortic valve, toward the ventricle. Of grave import are the perforations and rupture of the valves which may result from the ulcerative process. In a similar way, rupture of the chordæ tendineæ may occur. Fragments of the valves or portions of the thrombotic deposits may be carried into the circulation as emboli.

Microscopical examination reveals constantly, both in the thrombotic deposits and in the substance of the valves, masses of bacteria, which are nearly always micrococci. Although the micrococci have been found in small blood-

¹According to statistics of malignant endocarditis collected and analyzed by Osler (*The Lancet*, March 7, 1885), the mitral valve alone was affected in 77 cases, the aortic valve alone in 53 cases, the aortic and mitral valves together in 41 cases, the heart-wall in 33 cases, the tricuspid valve in 19 cases, and the pulmonary valve in 15 cases. In 9 cases the affection was confined to the right heart, the tricuspid valve being involved 5 times and the pulmonic valve 4 times.

vessels in the valves, it is probable that they usually invade the endocardium from its free surface, being deposited from the blood within the heart. The immediate effect of the invasion of the endocardium by the micrococci is to cause the foci of necrosis which have already been mentioned. Outside of the necrotic patches, which are mostly or wholly devoid of nuclei, there appear emigrated white blood-corpuscles, which wander into the necrosed tissue.

The bacteria which are present in acute ulcerative endocarditis are not always of the same nature. Both staphylococci and streptococci have been observed, and in most cases these organisms seem to be identical with those found in pus. It is possible to produce artificially lesions identical with those of acute ulcerative endocarditis, by injecting into the blood of animals certain of the micrococci which have been cultivated from pus, after having first mechanically injured the endocardium.¹

Acute ulcerative endocarditis is particularly prone to affect valves which are already diseased, but it may occur, apparently without previous lesion of the endocardium.

Inasmuch as the emboli which are swept off from the endocardium in this disease contain infectious bacteria, they produce necrosis, and usually abscesses, wherever they lodge. The emboli of simple endocarditis, on the other hand, produce only mechanical effects, being non-infectious or bland emboli. Among the most frequent complications of acute ulcerative endocarditis, therefore, are multiple abscesses in the kidneys, the spleen, and other parts of the body.

Petechiæ are often found in the skin in this disease. Sometimes, but not always, it is possible to demonstrate colonies of micrococci in the capillaries in or near the hemorrhagic tissue.

It is less easy than might be supposed to draw a sharp line of distinction between acute simple and acute ulcerative endocarditis. The macroscopical appearances may be the same in both diseases. Some pathologists hold that all forms of acute endocarditis are of mycotic origin. The weight of evidence, however, is in favor of the view that acute endocarditis may occur without the presence of bacteria.

Acute ulcerative endocarditis may occur as a primary affection. How, in this case, the bacteria enter the blood is not known. More frequently the disease is secondary to some infectious process, particularly puerperal fever, pyæmia, and acute articular rheumatism, less often pneumonia, dysentery, diphtheria, variola, scarlet fever, and typhus and typhoid fevers. It is not necessary to suppose that the specific organisms of all these infectious diseases are capable of causing malignant endocarditis, but it is more probable that the endocarditis is due in many cases to secondary infection with some form of micrococcus. We know that such mixed infections are not rare in the class of diseases which here come into consideration.

In acute ulcerative endocarditis occurring as a secondary affection in connection with acute rheumatism, puerperal fever, and pyæmia, the symptoms referable to the endocardial affection are commingled with those of the associated diseases, and the affection is liable to be overlooked. If endocardial murmurs

¹ In several instances of acute ulcerative endocarditis the *Staphylococcus pyogenes aureus* has been found and cultivated. Wyssokowitsch produced artificially acute ulcerative endocarditis by injecting, after lesion of the valves, various forms of bacteria, the most important being *Staphylococcus pyogenes aureus* and *Streptococcus pyogenes* (p. 91). Ribbert was able to produce, experimentally, mycotic endocarditis and myocarditis, without preliminary injury of the endocardium, by injecting cultures of *Staphylococcus pyogenes* grown on potato. The material injected contained particles of the potato, which formed emboli.

be ascertained, they may be supposed to denote only simple endocarditis. Subjective phenomena referable to the heart are not marked and are often wanting. The prominent symptoms are attributable to infective matter contained in the blood. Following an initial chill there is high fever, with notable remissions, the latter occurring irregularly or sometimes simulating those of periodical fever. There may be repeated chills; vomiting and diarrhœa are frequent symptoms; jaundice occurs not infrequently; purpuric spots on the skin are of frequent occurrence; prostration is great; and death is preceded by delirium and coma. Local symptoms in other organs than the heart arise from infective emboli. The affection being generally seated in the left side of the heart, emboli are carried to the spleen and kidneys. The spleen becomes enlarged and tender on pressure. Albuminuria may be present with or without renal embolism, and hæmaturia sometimes occurs. In exceptional cases the right side of the heart is the seat of the affection, and then embolic abscesses may be produced in the lungs. The symptomatology in some cases is suggestive of typhoid fever, and in other cases it accords with that of pyæmia, so that the disease has been considered as presenting two types, denominated typhoid and pyæmic.

When the disease is secondary to pyæmia it is not easy to determine whether the pyæmic symptoms be referable in any measure to the heart. Practically, this question is not one of much moment. The symptoms which have been enumerated, occurring in cases of acute rheumatism and connected with the physical signs of endocarditis, point to this endocardial affection. Further evidence of its existence is afforded by the rapid production of regurgitant lesions of the aortic or the mitral valve, provided it be known that these lesions were not present prior to the occurrence of the attack of rheumatism. The diagnosis, when the disease is primary, can be made with more positiveness. It is to be based on the symptoms and signs of an endocarditis followed by the general and local symptoms which denote pyæmia. Pre-existing valvular lesions of the heart, however, render it difficult to decide as to a recently developed endocarditis, so that under these circumstances the diagnosis is not easy. [The embolic manifestations in the skin are the signs which are the most diagnostic of this disease, but, unfortunately, they are not present in all cases. They usually appear as petechial spots with clear yellow centres, sometimes as pustules or pemphigoid bullæ. Circumscribed gangrene of the skin and suppuration of the matrix of the nail have also been observed, and are the result of minute infectious emboli. The eye-ground should be frequently examined for hemorrhages in cases of suspected ulcerative endocarditis. Retinal hemorrhage is extremely rare in typhoid fever—a disease with which ulcerative endocarditis is often confounded. In cases of typhoid type the stools and the blood of the petechial spots should be examined for typhoid bacilli. When endocarditis assumes the intermittent type the blood should be examined for the plasmodium malarizæ, the absence of which would furnish negative evidence of great value.—H.]

It is not known that recovery from acute ulcerative endocarditis ever takes place. With a prognosis based on this fact, all that can be done in the way of treatment, with our present knowledge, is to be guided by symptomatic indications and to endeavor to obviate the tendency to death. [In short, the treatment of ulcerative endocarditis is practically that of septicæmia. Sodium salicylate, sodium benzoate, and corrosive sublimate have been given with the object of destroying the micro-organisms in the inflamed tissues, but it is doubtful whether they possess the slightest efficacy in this respect. In a case of Eichhorst's which terminated in recovery, the diagnosis being

apparently correct, the medical treatment consisted chiefly of a pill composed of hydrochlorate of quinia and corrosive sublimate.]

Myocarditis—Diseases of the Coronary Arteries.

Inflammation of the muscular structure of the heart is called myocarditis. Various forms of myocarditis are distinguished, but that form which is of the greatest clinical importance is the variety called *chronic interstitial*, or *fibrous myocarditis*, and fibroid degeneration of the heart.

In the most important class of cases of fibrous myocarditis the primary lesion is not inflammation, but is atrophy or necrosis of muscular fibres of the heart in consequence of obstruction to the circulation in the coronary arteries. Lesions of the coronary arteries causing obstruction are of great clinical and pathological importance. The most common of these lesions is atheroma with calcification. Another lesion is obliterating endarteritis, which is not rare in syphilis and may also occur in other conditions. In consequence of disease of the arterial coats thrombi may form in the affected vessels, and, as the anastomoses of the coronary arteries are few, infarctions follow this complete obstruction. Less frequently, emboli enter the coronary arteries and lead to similar results. Infarctions in the heart may be either hemorrhagic or anæmic necrotic infarctions. If the emboli be infectious, as in acute ulcerative endocarditis, they cause abscesses in the myocardium. If life be sufficiently prolonged, the infarctions are replaced by cicatricial fibrous tissue. Some of the fibrous plaques found in the cardiac muscle are the result of such infarctions. More frequently the obstructions resulting from disease of the coronary arteries are not sufficient to cause typical infarctions, but they cause simple atrophy of the muscular fibres in circumscribed, scattered patches. This atrophy is followed by a new growth of fibrous tissue. According to a view which has much in its support, most of the chronic interstitial inflammations of organs are due to a primary atrophy of the parenchymatous elements.

In the form of fibrous myocarditis, here considered, which is due to disease of the coronary arteries, grayish-white, glistening streaks and patches of fibrous tissue are found scattered through the substance of the myocardium. These streaks and patches may be in any part of the muscular wall of the heart, but they are most frequently found in the anterior wall and apex of the left ventricle and in the papillary muscles. They affect by preference the outer layers of the myocardium, but they may be most abundant near the endocardium.

Another variety of fibrous myocarditis is that which is secondary to fibrous thickening of the endocardium or of the pericardium. Here new-formed connective tissue grows from the thickened endocardium or pericardium into the subjacent muscular tissue, leading to compression and atrophy of the muscular fibres.

In both forms of fibrous myocarditis the heart-wall is weakened, often sufficiently to yield to the blood-pressure and to cause cardiac dilatation. A spot in the heart-wall thus weakened by fibrous growth may bulge out in a sacculated manner and form an aneurism. This is the usual method of development of the so-called chronic partial aneurism of the heart. Such aneurisms are most frequently seated near the apex of the left ventricle, more rarely at the base of the ventricle, where they occupy by preference the situation of the pars membranacea septi, in the latter case bulging into the right ventricle. They may lead to rupture of the heart.

Thrombi are often found in these aneurisms as well as upon portions of the endocardium overlying infarctions and fibrous plaques.

When hypertrophy of the heart is present in cases of fibrous myocarditis, the cause of the hypertrophy is to be sought in concomitant valvular disease or widespread arterio-sclerosis or chronic Bright's disease. Hypertrophy of the right ventricle may be due to insufficiency of the left, in consequence of myocarditis.

In syphilis, patches of fibrous tissue may be found in the heart-muscle with or without the presence of gummata. Whether in such cases the fibrous myocarditis be always dependent upon obliterating arteritis or other arterial disease is uncertain.

Other forms of myocarditis are of less clinical importance. *Acute interstitial myocarditis*, rarely diffuse, more commonly circumscribed, characterized by an accumulation of lymphoid cells, may occur in diphtheria and other acute infectious diseases.

Better understood is *suppurative myocarditis*, or abscess of the heart. The abscesses are usually small and multiple, but a single large abscess may be formed. The most frequent cause of cardiac abscesses are infectious emboli, especially those derived from acute ulcerative endocarditis. The pus may be discharged into the pericardial sac, giving rise to purulent pericarditis, or into one of the cavities of the heart. In the latter case the blood makes its way into the abscess-cavity, thus leading to the formation of acute cardiac aneurism. Acute aneurism may also be produced by deep ulcerations in cases of acute ulcerative endocarditis. Rupture of the heart may be a result of suppurative myocarditis. Micrococci are present in the pus of cardiac as well as of other abscesses, and are to be regarded as the cause of the suppuration.

Some authors assume the existence of a parenchymatous myocarditis; but the changes which are described as belonging to parenchymatous myocarditis are in reality those of albuminous or fatty degeneration of the muscle, and will be described subsequently.

It should be mentioned that extensive disease, particularly atheroma, of the coronary arteries may exist without causing changes in the cardiac muscle. In such cases it is probable that the circulation is not sufficiently obstructed to lead to the changes which have been described, and to which, as will subsequently appear, fatty degeneration of the heart-muscle is to be added.

In all cases of sudden death without other explanation careful examination should be made of the condition of the coronary arteries.

It may be inferred that the myocardium is the seat of lesion of some kind when cardiac symptoms denote something more than functional disorder, and when enlargement from other causes, pericarditis, endocarditis, and valvular lesions can be excluded.

The effect of obstruction of the coronary arteries and fibroid degeneration of the heart is impairment of its functional power. If this effect exceed a certain degree, the symptoms denote persistent weakness of the heart's action. The pulse is feeble, compressible, and often irregular, and in some cases is notably infrequent. Dyspnoea, at first felt only on exercise, may become constant, ending at length in orthopnoea. With notable disturbance of respiration is associated lividity of the prolabia and face. General dropsy may occur, and death may take place slowly, as in cases of dilatation.

The physical signs denote weakness of the heart's action, usually with more or less enlargement of the organ. Cardiac impulse is feeble or wanting. The murmurs indicative of valvular lesions are not present, and these lesions may be thereby excluded. The sounds of the heart are weak. The sound of impulsion over the apex especially is weak, and may not be appreciable, the systolic sound being chiefly or entirely valvular in quality.

The differential diagnosis lies between myocarditis, with obstruction of the

coronary arteries, fatty degeneration, and a purely functional disorder. The last-named affection is excluded by the persistence of the symptoms pointing to heart-failure. The symptoms of fatty degeneration are essentially identical, and this affection is not therefore easily excluded. Practically, this is not important. The fact that the patient has had syphilis is in favor of myocarditis. Calcification of arteries which can be felt is suggestive of a similar alteration of the coronary arteries, but is not conclusive evidence.

Sudden death is liable to occur in cases of myocarditis associated with obstruction of the coronary arteries. This may follow violent physical exertion, although not preceded by symptoms denoting any important cardiac affection.

Angina pectoris occurs in connection with obstruction of the coronary arteries, either with or without fibroid degeneration of the heart. Sudden death is liable to occur without as well as with an attack of angina.

The TREATMENT in cases of myocarditis is essentially the same as in cases of dilatation of the heart. (Vide Chapter III.) The objects of treatment relate to symptomatic indications and tolerance. Avoidance of active physical exertion and mental excitement is to be enjoined. Assimilation and nutrition are to be promoted by a nutritious diet and tonic remedies. The iodides and arsenic have been supposed to have a favorable influence. The former are indicated if there be evidence of constitutional syphilis. Impending danger from heart-failure is to be warded off by alcoholic or ethereal stimulants.

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters ; Clinical History ; Pathological Character ; Causation ; Diagnosis ; Prognosis ; Treatment.

THE structural lesions of the heart relate, in the first place, to the valves and orifices of the heart. These are known commonly as *valvular lesions*. Other lesions relate to the walls and cavities of the heart. Enlargement of the heart often proceeds from valvular lesions, and the latter sooner or later, in the great majority of cases, give rise to enlargement. In considering, therefore, valvular lesions, I shall also consider enlargement as dependent thereon, and afterward notice enlargement occurring without valvular lesions.

ANATOMICAL CHARACTERS.—Valvular lesions, in the great majority of cases, are due to chronic endocarditis. When developed after birth, they are nearly always situated in the left side of the heart ; that is, at the mitral or the aortic orifice. Tricuspid and pulmonic lesions are comparatively rare in extra-uterine life. Rheumatic endocarditis most frequently attacks the mitral valve. With chronic inflammation of the aortic valve an atheromatous condition of the neighboring portion of the aorta is usually present, the processes in the valves and in the inner membrane of the aorta being essentially similar. Aortic lesions therefore, like atheroma, are more frequent in advanced life than in youth. Chronic endocarditis of the aortic valve is often associated with a similar change in the mitral, particularly in its aortic, segment. The changes in the endocardium produced by chronic inflammation have

already been referred to in treating of endocarditis. The morbid process in the valves may begin either acutely or subacutely, or it may develop slowly and insidiously. The essential change is the formation, in the substance of the valve, of new fibrous tissue of firm consistence and with a marked tendency to retract. The thickening is usually most marked along the edges of the valves, where warty outgrowths of fibrous tissue are frequently observed. Calcification and fatty degeneration of the new connective tissue are often extensive. The anomalies in the valves resulting from these changes are—1, thickening and rigidity due to the formation of new connective tissue and the deposit of the salts of lime; 2, shortening in consequence of retraction of the newly-formed tissue; 3, adhesion of the valvular segments to each other or to the heart- or vessel-wall; 4, valvular aneurisms and rupture of the valves. Shortening, rigidity, and sometimes rupture of the chordæ tendinæ may coexist. Deposits of thrombi may be present on the thickened and calcified valves, and serve as a source of emboli. Emboli may also be formed by ruptured fragments of the valves or by the breaking off of calcific incrustations. The thickened valvular segments are sometimes united at their sides to such an extent as to leave only a buttonhole-like slit sufficient for the admission of the end of the little finger, or sometimes, in the case of the aortic valves, for the passage only of a crow's quill.

The importance of these various changes lies in the fact that they constitute the vast majority of those structural alterations which interfere with the function of the valves. From a clinical point of view all the diverse alterations of structure embraced under the name valvular lesions may be arranged, according to their effects upon the circulation, into the following groups: *First*, obstructive lesions—that is, lesions which impede the flow of blood by producing contraction or stenosis of the orifices; *second*, regurgitant lesions—that is, lesions which render the valves incompetent or insufficient, consequently allowing backward or regurgitant currents; *third*, lesions which involve both obstruction and regurgitation; and *fourth*, lesions which involve neither obstruction nor regurgitation, but which give rise to morbid sounds by roughening the surface over which the blood flows. The lesions belonging to the last group are of little or no immediate importance, and, although giving rise to abnormal sounds known as endocardial or bellows murmurs, they are innocuous. The most frequent form of lesion is that which occasions both obstruction and insufficiency at the same time, one or the other of these effects frequently preponderating. Obstruction unaccompanied by any regurgitation is rare, while regurgitation without obstruction is not infrequent. In certain instances we must recognize the existence of so-called *relative insufficiency* of the valves. This is incident to cases of marked dilatation of the heart-cavities, the ostia becoming so wide that the unchanged valvular segments are incapable of completely closing the dilated orifices. This condition is met with most frequently at the tricuspid orifice in cases of extreme dilatation of the right ventricle as a consequence of mitral disease.

The lesions which involve obstruction or regurgitation lead primarily to certain changes in the heart itself, and secondarily to alterations in various other organs of the body. These changes in the heart are at first of a nature to compensate more or less completely the impairment of function of the valves. The mechanical effects of obstruction or of regurgitation at any of the valvular orifices, when not compensated, are a diminution in the amount of blood supplied to the aorta and general arterial system and a corresponding over-repletion of the systemic veins. These effects are produced by stenosis and by insufficiency from valvular disease of either the left or of the right side of the heart. The blood-pressure in the systemic arteries is therefore lessened, while that in the veins is increased; and the

result is retardation of the general circulation. These effects of impaired function of the valves are at first more or less completely compensated by increase in the capacity and the strength of certain portions of the heart. Certain cavities dilate and their walls become hypertrophied, so that, notwithstanding the valvular defects, the arteries of the body receive their proper amount of blood. During what may be termed the period of compensation the hypertrophy bears a harmonious relation to the dilatation; when the compensation becomes disturbed or destroyed, the dilatation exceeds in proportion the hypertrophy. During the stage of compensation, which may last for years, the individual suffers but little inconvenience from the valvular lesions. Sooner or later, in the majority of cases, the compensation is disturbed, and various characteristic symptoms and morbid changes ensue.

In order to understand the changes in the heart it is well to consider individually the different valvular lesions as to their effects. In cases of insufficiency of the mitral valve (the most frequent of all valvular lesions), during the systole of the left ventricle a portion of the blood is sent back into the auricle, and the aorta receives a proportionately smaller amount of blood. During the diastole an abnormally large amount of blood flows into the left ventricle in consequence of the over-accumulation in the left auricle and the pulmonary veins. The left ventricle is thereby over-filled, and as a consequence its wall becomes hypertrophied. At the same time the left auricle becomes dilated and hypertrophied; but the hypertrophy of the thin-walled auricle cannot compensate the over-accumulation of blood. The blood is therefore dammed back upon the pulmonary veins, whence the increase of tension is transmitted through the pulmonary vessels to the right ventricle. This becomes over-distended with blood, and in turn it becomes hypertrophied. Mitral insufficiency is thus compensated by the hypertrophy of the two ventricles, so that notwithstanding the regurgitation at the mitral valves a normal amount of blood is transmitted into the aorta. The muscular coat of the auricles is so thin that they can accomplish but little in the way of compensating valvular lesions. It may be that the compensation for mitral insufficiency is so complete that the patient suffers for a considerable period no inconvenience. When the compensation is destroyed the dilatation becomes excessive, the right auricle becomes over-distended, and the blood is dammed back upon the general venous system. The effects of this venous congestion of the various organs and parts of the body will be presently described.

In mitral stenosis less blood than normal flows into the left ventricle through the contracted orifice during the diastole. The blood accumulates in the left auricle, which dilates and becomes hypertrophied. The blood-pressure, as in mitral regurgitation, increases in the pulmonary vessels, and consequently the right ventricle becomes over-filled and hypertrophied. Inasmuch as the left auricle and right ventricle are rarely able to completely compensate the obstruction, the left ventricle receives less than the normal amount of blood, and, being called upon to do less work, it becomes atrophied. Mitral stenosis unaccompanied by regurgitation and consequent hypertrophy of the left ventricle, however, is rare. It will be observed that while mitral regurgitation is compensated by hypertrophy of both ventricles, mitral stenosis is compensated essentially by hypertrophy of the right ventricle, and is less fully counteracted.

The immediate result of insufficiency of the aortic valves is that during the diastole a portion of the blood which had been driven into the aorta by the systole flows back into the left ventricle. The ventricular cavity is thereby over-filled and its wall becomes hypertrophied, so that by its increased power of contraction the excessive amount of blood which accumulates in the left ventricle during the diastole can be forced into the aorta.

In this way the arteries can receive their normal quantum of blood notwithstanding the regurgitation. No valvular lesion, as a rule, is more completely compensated than aortic insufficiency. In consequence of the backward flow of blood from the aorta the left auricle cannot empty itself as readily as usual, and it therefore dilates and becomes hypertrophied. The blood is then dammed back upon the lungs, and, as in the previous instances, the right ventricle becomes hypertrophied and dilated. The tension in the right ventricle may be still further increased by simultaneous involvement of the mitral valve in the endocarditic process, or rarely by relative insufficiency of the mitral valve.

In aortic stenosis the left ventricle, being unable to completely empty itself, becomes hypertrophied and dilated. The degree of dilatation, however, is usually less than in cases of aortic insufficiency. Dilatation and hypertrophy of the left auricle and of the right side of the heart are produced in the same way as in the valvular lesions already described. The most extensive enlargements of the left ventricle met with are those consecutive to aortic insufficiency accompanied with moderate stenosis. Aortic lesions are situated more favorably as regards completeness of compensation than mitral, because the former defects are counteracted by hypertrophy of the ventricle immediately behind the valves, while the latter require hypertrophy of the opposite ventricle, to which the increase of tension must be transmitted through the pulmonary vessels. When, however, the compensation of aortic lesions becomes disturbed—in other words, when the left ventricle is no longer able to meet the increased demands upon its strength—the grave symptoms of venous stagnation follow with greater rapidity than after disturbance of the balance in mitral lesions.

After birth, relative insufficiency of the tricuspid valve is more frequent than insufficiency due to chronic endocarditis of the valve. In either case the affection is usually secondary to disease of the left ventricle. As the result of tricuspid regurgitation, less blood than normal is sent to the pulmonary vessels, and therefore the pressure in the pulmonary veins and that in the aorta are abnormally diminished. On the other hand, in consequence of the over-accumulation of blood in the right auricle the right ventricle is filled under increased pressure. Hypertrophy and dilatation of the right auricle and of the right ventricle ensue in the same way as enlargement of the opposite cavities in mitral regurgitation. In uncomplicated tricuspid regurgitation the left ventricle does not enlarge, because the pressure in the pulmonary veins is not increased, and the aortic tension is not elevated, notwithstanding the regurgitation of blood into the general venous system. Tricuspid regurgitation is therefore imperfectly compensated.

Stenosis of the tricuspid valve, unaccompanied by insufficiency, has been observed only as a result of foetal endocarditis. Uncomplicated tricuspid stenosis belongs among the curiosities of medical experience. It is the most unfavorable of all valvular lesions as regards compensation. It can be only very imperfectly compensated by dilatation and hypertrophy of the right auricle, all of the other cavities of the heart receiving less than the normal amount of blood, and therefore becoming atrophied. Tricuspid stenosis, as a rule, is accompanied by other valvular lesions.

Stenosis and insufficiency of the pulmonic valves are well-recognized forms of congenital valvular disease. Still, they are very rare. When of foetal origin they are often complicated with other anomalies, such as stenosis of the pulmonary artery or of the conus arteriosus, perforation of the septum ventriculorum, and non-closure of the foramen ovale or of the ductus Botalli. When uncomplicated they are compensated, often completely, by dilatation and hypertrophy of the right auricle and ventricle. The left side of the

heart does not enlarge, but, on the other hand, it has been found atrophied. These lesions may develop in very rare instances as a sequence or concomitant of chronic endocarditis of the left side.

We have now considered the mechanism of the production of the primary changes in the heart following valvular lesions. It has been shown that the different lesions may be compensated to a greater or less extent by hypertrophy and dilatation of certain cavities of the heart. The dilatation is mechanically produced by over-accumulation of blood; the hypertrophy is the result of augmented nutrition of the muscular wall consequent upon the demand for increased activity of the heart. In favorable cases the hypertrophy bears a certain definite relation to the dilatation and to the degree of obstruction or regurgitation, so that the functional defects of the valves are as nearly counteracted as may be. In unfavorable cases, even very early, the dilatation may so predominate over the hypertrophy that the valvular lesion may never be as fully compensated as is possible. This is likely to be the case in persons very much enfeebled, especially when the valvular defects are acutely developed.

In nearly all valvular lesions, either early, or, more frequently, after a variable period of compensation, the dilatation comes to bear an excessive ratio to the degree of hypertrophy, and the blood is dammed back upon the general venous system. Changes ensue referable to chronic venous congestion or passive congestion of various parts of the body. A knowledge of these changes is necessary to a proper understanding of the symptoms common to uncompensated valvular lesions. They can only be referred to briefly here, as their description belongs to other sections of this work.

The compensation is sometimes disturbed by extension of the morbid processes in the valves, and in many cases it is impaired by fatty degeneration of the hypertrophied muscular tissue. Depression of the general vitality of the patient and the occurrence of intercurrent disease likewise enfeeble the heart. In some cases, however, the cause of the failure of the heart is not evident.

In the lungs, as a result of chronic venous congestion, the condition already described as brown or pigment induration is developed (p. 96). In this state the pulmonary capillaries are distended and encroach upon the air-cells. Hemorrhagic pulmonary infarctions are frequent, produced by emboli in branches of the pulmonary artery (p. 186). These emboli are derived usually from thrombi formed in the right side of the heart. It is not rare in the later stages of valvular disease for thrombi to form, especially in the apices of the ventricles and in the auricular appendices, in consequence of the retardation of the blood-current. Chronic bronchitis usually attends valvular lesions of the left side of the heart. The condition of the heart during the stage of non-compensation is particularly favorable for the production of œdema of the lungs.

In consequence of chronic passive congestion the condition called nutmeg liver is developed. The blood being dammed back upon the inferior vena cava and hepatic veins, the central veins of the hepatic lobules become distended, and the lobules present a red centre and light periphery. In the peripheral zone the hepatic cells often contain fat. This swollen state of the liver may be followed by a so-called red atrophy of the organ—a condition to be hereafter described in Section IV.

Chronic congestion of the spleen is evident after death from its enlargement, dark color, and firm consistence. The kidneys are enlarged, and in typical cases of extremely hard consistence and of a dark-red color. This condition was formerly mistaken for chronic interstitial nephritis. The albuminuria of cardiac disease is explained by increase of pressure in the renal

veins and consequent slowing of the circulation, and the diminution in the amount of urine excreted, by the diminished tension in the renal arteries. Chronic congestion of the alimentary tract may induce chronic inflammation of the stomach and intestine. Cyanosis and anasarca, with transudation of serum into the various serous sacs of the body, result from the general venous congestion. In consequence of the retardation of the general circulation the blood may coagulate in the peripheral veins and venous sinuses of the body. Thrombi so formed are called *marantic*. They form an additional source of origin for emboli which are carried to the pulmonary artery. Venous hyperæmia and arterial anæmia of the brain are among the consequences of uncompensated valvular lesions. The lodgment of emboli in the cerebral arteries, particularly in the middle cerebral or its branches, and the consequent softening of the anæmic portion of the brain, will be considered in Section V.

CLINICAL HISTORY.—Valvular lesions, so long as they involve neither obstruction nor regurgitation, give rise to no symptoms of disease, and their existence is only ascertained by means of physical signs. Lesions involving either obstruction or regurgitation, or both, as a rule do not occasion inconvenience until they have led to enlargement of the heart. Moreover, lesions occasion suffering and are attended with danger in proportion as the dilatation predominates over the hypertrophy.

The first symptoms proceeding from *mitral obstructive or regurgitant lesions* pertain to the respiratory system. Deficiency of breath on exercise is for some time the chief inconvenience. This progressively increases in proportion as the obstruction to the pulmonary circulation increases. The patient is at length obliged to discontinue any active muscular exertion, but may be comfortable while remaining quiet. Dyspnœa finally becomes habitual, and is more or less prominent as a symptom after dilatation of the right ventricle has taken place. A still further development of this symptom renders the patient unable to lie down, then constituting *orthopnœa*. This may be due, in a measure, to coexisting pulmonary conditions. Cough and more or less muco-serous expectoration are incidental to congestion or a low grade of inflammation of the bronchial mucous membrane. An abundant serous expectoration sometimes occurs, constituting *bronchorrhœa*. *Hæmoptysis* is not infrequent, the hemorrhage usually being small. This event generally denotes simply *bronchorrhagia*, but occasionally blood is extravasated into the air-cells, constituting circumscribed pulmonary apoplexy or hemorrhagic infarction. Pulmonary œdema is another intercurrent event which is liable to occur, increasing the suffering from dyspnœa. Hydrothorax is still another source of embarrassment of respiration. Pigment induration of the lungs dependent on persistent congestion, caused by regurgitant and obstructive mitral lesions, enters into the rationale of dyspnœa in many cases.

After enlargement of the heart takes place, its action, so long as the hypertrophy predominates, is abnormally strong. This may be perceived by the hand placed over the *præcordia*. The patient, however, rarely complains much of palpitation, having become accustomed to the gradual increase of the power of the heart's action. The pulse is small and weak in proportion to the amount of obstruction or regurgitation, each of these immediate effects of the lesions lessening the quantity of blood propelled into the aorta and its branches by the systole of the left ventricle. The quantity of blood contained in this ventricle at the time of a systole may sometimes be so much lessened that it fails to produce a radial pulse; hence one source of intermission of the pulse. Another source is an actual intermission of the ventricular systole. Inequality of the successive beats of the pulse, as regards volume and force, represents *unequal* supplies of blood from the left auricle to the left ventricle. Irreg-

ularity in the action of the heart is not infrequent. Intermittency of the pulse and inequality of successive beats, due to deficiency of the supply of blood to the left ventricle, are characters which denote mitral contraction rather than regurgitation.

The characters pertaining to the form of the pulse, as ascertained by the sphygmograph, in cases of mitral regurgitation, are—noticeable variations in the length of the line of ascent in different pulsations, shortness of this line in a greater or less number of pulsations, its vertical direction, and marked diastolicity in the line of descent. In cases of mitral obstruction the line of ascent is longer and the variations in different pulsations are less, the direction of this line being also vertical, and the line of descent showing diastolicity. These characters denote quickness of the ventricular systole, feeble arterial tension, and want of uniformity as regards the quantity of blood sent into the aorta in different beats.

Pain is rarely a prominent symptom during the progress of mitral lesion, but uneasiness and an indefinite sense of distress, referred to the præcordium, may be complained of. Nor are there any notable symptoms referable to the nervous system. There is a marked contrast, as regards mental anxiety and apprehension, between the cases in which the action of the heart is disturbed by lesions and those in which the disturbance is purely functional. In the former mental depression is proportionate to the physical suffering, and patients are likely to be apathetic with respect to danger; in the latter the mind is depressed out of proportion to the actual ailment and patients are harassed by imaginary fears. If dyspnoea be a prominent symptom, the loss of sleep adds to the sufferings of the patient. The sleep which is obtained is imperfect and disturbed by frightful dreams. It is not uncommon for patients to be unable to lie down for many weeks before death, short periods of sleep being obtained by inclining the body forward and resting the elbows on the knees or on some solid support.

Sooner or later, if life be not cut off by some intercurrent affection, dropsical effusion takes place into the areolar tissue and serous cavities. The lower limbs generally first become oedematous, afterward the face and body, and more or less liquid accumulates within the peritoneal and within the pleural sac. The limbs and body sometimes become greatly swollen and the scrotum acquires an enormous size. The skin on the lower limbs under these circumstances may become erythematous; ulcerations or fissures are liable to occur with abundant draining away of serum. Other circumstances, in addition to dilatation of the right side of the heart, may contribute to the occurrence of dropsy; for example, anæmia. The face is congested, and not infrequently the lips are livid. The dusky hue, due to congestion or cyanosis, combined with oedema, gives to the face an appearance which contrasts with the pallid aspect characterizing general dropsy from renal disease. General dropsy arising from mitral lesions occurs after enlargement by dilatation of the right side of the heart has taken place, and is dependent mainly on the venous obstruction which the latter condition involves. Tricuspid regurgitation, which may exist to some extent normally, is increased in this condition, and adds to the venous obstruction. This condition of the right cavities gives rise to turgescence of the cervical veins, especially when the patient is sitting or standing, and the turgescence is sometimes very great. Under these circumstances pulsation of the superficial veins of the neck, occurring synchronously with the auricular or ventricular systole, or with both, is not uncommon. Jugular pulsation is, however, observed in some cases without venous turgescence, and when dropsy has not taken place venous pulsation of the veins of the extremities is sometimes observed.

The organs composing the digestive system suffer from the congestion arising

ing from dilatation of the right side of the heart. Enlargement of the liver is sometimes observed. Pulsation over the liver, apparent to the eye and touch, is an occasional effect of tricuspid regurgitation with hypertrophy of the right ventricle. The pulsation is sometimes so strong as to simulate aneurism. The appetite and digestion become impaired. Prior to the occurrence of dilatation, however, the appetite and digestion may be but little disturbed. Nutrition may be but little affected even after the lesions have led to considerable suffering. Emaciation is not an early, nor at any time a marked, effect of valvular lesions of the heart. The kidneys participate in the congestion, and the secretion of urine is scanty. Albumen may be present in the urine as an effect of renal congestion without denoting degenerative or inflammatory disease of the kidneys. Hemorrhage from the stomach or intestines is an occasional effect of the congestion of the mucous membrane in these situations. Hemorrhoids and epistaxis belong in the same category.

Aortic lesions involving obstruction or regurgitation usually give rise, as the first symptom, to inconvenience from the increased power of the heart's action consequent upon hypertrophy of the left ventricle. The patient complains of palpitation, especially on exercise or under the influence of mental emotions. The action of the heart is felt, by the hand over the præcordia, to be inordinately strong, and the dress or portions of the body may show visible movements with each ventricular systole. Pain is more likely to be present than in cases of mitral lesions, and, irrespective of the painful affection called *angina pectoris*, it is not infrequently a prominent symptom. Cough, expectoration, dyspnoea, and hæmoptysis, dependent on pulmonary congestion and the accidents incident thereto, occur less frequently in connection with aortic than with mitral lesions. Pulmonary congestion, dependent on dilatation of the left auricle, does not occur until the dilatation of the left ventricle becomes predominant, and the disease may end fatally without this result taking place.

If the lesions produce contraction with little or no regurgitation, the pulse is simply weakened, but not in a notable degree even when the contraction is considerable. Under these circumstances, however, the pulse is frequently weak in proportion to the power of the heart's action; and the force of the stroke felt by the finger over the artery is in striking contrast to the impulse felt by the hand over the præcordia. If the lesions impair the aortic valve so as to involve considerable regurgitation, the pulse is somewhat distinctive of this fact. The artery strikes against the finger with quickness, and appears instantly to recede; the stroke is not sustained, and the pulse is said to be *jerk*ing or *collapsing*, giving a sensation as if a "ball of blood were shot through the artery." This is due to the fact that directly after the ventricular systole the aorta is emptied by the regurgitant current, and this current and the direct current come into collision when the ventricle contracts. Another symptom pertaining to the arteries in some cases is distinctive of free aortic regurgitation—namely, visible movements of the arterial trunks which are superficially situated, such as the carotid, temporal, subclavian, brachial, etc. The appearance caused by the movements of these vessels is sometimes very striking, and it is so distinctive that aortic regurgitation is rendered highly probable by this symptom alone.

The tracings by the sphygmograph in cases of aortic obstructive lesions give an oblique and curved line of ascent, denoting the slowness with which the blood is driven into the aorta, and in the line of descent dirotism is either slight or wanting. In cases of aortic regurgitation the line of ascent is vertical, and dirotism in the line of descent is marked. If, as is not infrequent, senile induration of the arteries coexist, the summit presents a plane of greater or less length. If this condition of the arteries do not exist, the

upper part of the diagram representing a pulsation is pointed, and the line ascendent may be notched near its upper extremity.

General dropsy occurs in only a small proportion of cases of aortic lesion that is, dropsy arising from the cardiac affection. This is owing to the fact that life is generally destroyed before the lesions have led to predominant dilatation of the right cavities of the heart. Hence, turgescence of the cervical veins and jugular pulsation do not belong to the clinical history of aortic lesions. This statement also holds good with respect to congestion of abdominal viscera and the kidneys.

Aortic regurgitant lesions give rise to symptoms proceeding from a sudden increase of the accumulation of blood within the left ventricle sufficient to embarrass the action of this ventricle by distension. This ventricle becomes overloaded by the regurgitant current in addition to the direct mitral current. The ventricular walls are distended so as to weaken their power of contraction. This is a rational explanation of paroxysms of distress to which these lesions give rise. The action of the heart is irregular and spasmodic, and the patient experiences a sense of great oppression at the præcordia, with a feeling impending death. These attacks are excited at first by muscular exercise and mental emotions, but after a time they may occur without any obvious exciting cause. They occasion great distress, and sudden death may take place in an attack of unusual violence, the left ventricle being paralyzed by over-tension. They are more frequent and serious when dilatation of the left ventricle predominates over hypertrophy, yet they may be more or less frequent and violent, and may prove fatal while hypertrophy is predominant. The occurrence of these attacks renders patients affected with aortic lesions more anxious and apprehensive than those affected with mitral lesions. The danger from over-distension of the ventricle is perhaps greater without than with mitral insufficiency. The latter, as regards this danger, may be said to be compensatory.

Aortic and mitral lesions, involving either obstruction or regurgitation, both, in each situation, are not infrequently associated in the same case. Certain of the symptomatic phenomena arising from lesions at the mitral and aortic orifice are then combined. Mitral obstruction as well as regurgitation, however, may afford some protection against the paroxysms of distress and the liability to sudden death incident to aortic regurgitation, by preventing over-distension and paralysis of the left ventricle.

Tricuspid and pulmonic lesions, as already stated, are comparatively rare. In the majority of cases in which they exist they are congenital. They are therefore most liable to be met with in young subjects. Tricuspid lesions, in proportion as they involve obstruction or regurgitation, lead primarily to dilatation of the right auricle, and thence to systemic congestion. General dropsy under these circumstances is likely to occur early, without having been preceded by the symptoms denoting pulmonary congestion. Turgescence of the cervical veins and venous pulsation are also early symptoms in such cases. Lesions at the pulmonic orifice, involving contraction or regurgitation, in like manner soon lead to dilatation of the right auricle and symptomatic phenomena dependent thereon.

PATHOLOGICAL CHARACTER.—The primary evils of valvular lesions are mechanical. They do harm by obstructing the direct or normal current of blood, and by allowing abnormal or regurgitant currents to take place. They induce hypertrophy or morbid growth of the walls of the heart by increasing the force of the heart's action, and thereby inducing hypernutrition. As a result, it is to be borne in mind, is not an evil. The hypertrophy resulting from valvular lesions is conservative. The augmented power of action with

the heart acquires with its increased muscular growth enables it better to carry on the circulation despite the obstacles afforded by obstructive and regurgitant lesions. The hypertrophy is compensatory for the obstacles which these lesions afford. This fact has an important practical bearing on the management. Dilatation of the cavities is another result of valvular lesions. This result, when it predominates over hypertrophy, is an evil. The heart is weakened in proportion as it becomes dilated. The circulation then suffers, not only from the obstacles afforded by the valvular lesions, but from the inadequate power of the heart's action. As a rule, it is not until dilatation predominates over the hypertrophy that distressing and grave symptoms of disease of the heart are developed; and the suffering and danger increase as the dilatation progresses.

It is important to bear in mind that valvular lesions do not necessarily involve existing inflammation. The atrophy and calcareous degeneration which lead to contraction of the valves, rigidity, rupture, etc. are not inflammatory processes, although they may be, and in a large proportion of cases probably are, the after-effects of inflammation.

CURATION.—In the majority of cases valvular lesions originate in an endocarditis occurring in acute articular rheumatism. The degenerative changes which follow endocarditis lead to obstruction or regurgitation after a period more or less remote. When the evils or inconvenience resulting from valvular lesions are sufficient to lead the patient to seek for medical aid, it may be found that one or more attacks of rheumatism were experienced five, ten, fifteen, or twenty years before; and when cases first come under observation more or less enlargement of the heart has already taken place. Enlargement, indeed, has probably existed for a long time, and it may not be until the heart becomes weakened by dilatation that the patient applies to the physician. Moreover, rupture of the valves or tendinous cords sometimes results from the violence of the heart's action, without any previous structural change. Rheumatic endocarditis affects by preference the mitral valves. The congenital lesions generally affect the valves of the right side. On the other hand, chronic inflammation of the aorta, leading to an atheromatous condition, is likely to involve the aortic valves. These lesions are more frequent in advanced than in early life, whereas the mitral lesions consequent on rheumatic endocarditis are oftener manifested in the latter period. Chronic non-rheumatic endocarditis, however, often affects both the aortic and the mitral valves, more especially the aortic segment of the latter. Valvular lesions occur not infrequently as a remote effect of syphilis.

DIAGNOSIS.—The existence of valvular lesions can be determined with positiveness only by means of auscultatory signs. By means of signs the existence of lesions, their situation, and their character as regards being obstructive or regurgitant may generally be ascertained. Lesions situated at the different valves and orifices are represented by endocardial murmurs, and the presence of these is evidence of the existence and situation of the lesions. It will suffice here to enumerate the several organic murmurs produced within the heart, together with the distinctive characters and significance of each. They are naturally arranged into mitral, aortic, tricuspid, and pulmonic murmurs.

Mitral Murmurs.—A murmur heard with the first sound of the heart—*i. e.* systolic, having its maximum of intensity at or near the situation of the apex-beat, or perhaps limited to that situation—represents mitral lesions. These lesions may or may not involve insufficiency of the valve and consequent regurgitation. If a regurgitant current exist, the murmur is properly called

a *mitral regurgitant murmur*; but as mere roughness of the valve probably may give rise to a murmur with the characters just mentioned, without regurgitation, the name just given is not always strictly correct. A better name is *mitral systolic murmur*, with or without regurgitation. If the murmur be diffused beyond the apex, around the left lateral surface of the chest, and heard on the back near the lower angle of the scapula on the left, and sometimes on the right side, mitral regurgitation may be inferred. If the murmur be heard only around the apex and over the body of the heart, it does not afford proof of regurgitation; it may be a mitral systolic, non-regurgitant, or an intraventricular murmur. A mitral systolic murmur, regurgitant or non-regurgitant, is not transmitted above the heart, and is not heard over the carotid arteries. This murmur may be soft (bellows-like) or rough, and sometimes it is musical. It is to be distinguished from a murmur sometimes produced by the impulse of the heart against the portion of lung covering the apex. This exocardial murmur is called a *cardiac pulmonary murmur*. It is usually limited to the inspiratory act and to a space over or a little to the left of the apex-beat.

A murmur heard after the second and just before the first sound of the heart—*i. e.* presystolic, continuing up to the first sound and instantly arrested when this sound occurs—also represents, generally, mitral lesions. This murmur is heard at or near the apex, and is usually confined within a circumscribed area around the apex. It is almost always rough, resembling a sound produced by throwing the lips or tongue into vibration with the expired breath. The letters *rrrp*, whispered, the tongue vibrating with the first three letters, represent the murmur, the letter *p* representing the first sound of the heart. This murmur is produced by contraction of the mitral orifice in consequence of the union at their sides of the mitral curtains, forming a buttonhole-like slit. The murmur represents mitral contraction with occasional exceptions. In some cases in which free aortic regurgitation exists, the left ventricle becoming filled before the auricles contract, the mitral curtains are floated out, and the valve is closed when the mitral current takes place. Under these circumstances the murmur may be produced, although no mitral lesion exists. I have reported cases in which this murmur was marked, the autopsy showing no mitral lesions, but aortic lesions permitting free regurgitation.¹ This murmur is called the *mitral direct or presystolic murmur*.

A mitral murmur, following the second sound of the heart and ending before the first sound, is produced by the current of blood from the auricle to the ventricle prior to the auricular contraction. This murmur may have the quality which usually characterizes the presystolic murmur, or it may be a soft blowing sound. It is heard at or a little above the apex. This murmur may be called the *mitral diastolic murmur*. It may be associated with the presystolic murmur, and the two murmurs will then occupy the whole of the long pause of the heart.

The murmurs produced by the direct and the regurgitant streams of blood not infrequently coexist. Either may exist without the others, the mitral regurgitant being much the more frequent.

Aortic Murmurs.—A murmur with the first sound, or a systolic murmur, heard with its maximum of intensity at or above the base of the heart and propagated into the carotids, is called an *aortic direct murmur*. This murmur may represent aortic lesions, and it is then called organic, or it may be

¹ Vide article on cardiac murmurs by the author in the *American Journal of the Medical Sciences*, July, 1862. A case in which a mitral presystolic murmur existed without mitral lesions, free aortic regurgitation existing, is reported by Dr. John Guiteras in the *Philadelphia Medical News*, Nov. 14, 1885.

due to a morbid condition of the blood, without aortic lesions, and it is then called an inorganic, an anæmic, or a hæmic murmur. The following circumstances render it probable that the murmur is inorganic or anæmic: The evident existence of anæmia; the absence of other signs of cardiac lesions; the variableness of the murmur, being sometimes present and sometimes wanting, and differing much at different times in intensity; the presence of murmur in the larger arteries, such as the carotid, subclavian, etc., and a continuous murmur in the veins of the neck, commonly known as the venous hum. Attention to these points will generally suffice for determining whether an aortic direct murmur be organic or inorganic. The organic murmur denotes lesion of some kind, but not necessarily obstructive; that is, the lesion may simply render the membrane at or near the aortic orifice rough, without involving obstruction to the current. The murmur may be soft or rough, and it is sometimes musical.

An aortic murmur with the second sound of the heart—*i. e.* diastolic, heard usually at the base, but in most cases having its maximum a little below the base, on or near the left margin of the sternum—is called an *aortic regurgitant murmur*. It represents insufficiency of the aortic valve, and consequent regurgitation from the aorta into the left ventricle. This murmur may be more or less loud and prolonged; it is generally soft, but sometimes rough, and it may be musical. According to Dr. Balthazar Foster, if the murmur be heard at the apex of the heart, it denotes that the insufficiency is due to a lesion of the posterior segment of the aortic valve.

A murmur is sometimes produced by the backward current of blood in the aorta, the aortic valves being sufficient; that is, regurgitation into the ventricle not taking place. This is a very short murmur, preceding and ending with the second sound. It is heard over the site of the aorta in the second right intercostal space, close to the sternum. It may be called an *aortic prediastolic murmur*.

The aortic direct and regurgitant murmurs not infrequently exist in combination, but either may be present without the other. Aortic murmurs coexist with mitral murmurs in the cases in which mitral and aortic lesions are associated.

Tricuspid Murmurs.—Tricuspid lesions are comparatively rare, and hence a murmur referable to this orifice is infrequent. A *tricuspid regurgitant murmur* occasionally exists, representing regurgitation from the right ventricle to the right auricle, with, perhaps, hypertrophy of the ventricle. It occurs with the first sound, and is to be distinguished from a *mitral regurgitant murmur* by its being either limited to, or having its maximum of intensity at, the right inferior border of the heart—namely, near the ensiform cartilage. It is liable, without care, to be confounded with a mitral regurgitant murmur. A tricuspid direct murmur is exceedingly rare, owing to the fact that lesions analogous to those which give rise to a mitral direct murmur are infrequent at the tricuspid orifice.

Pulmonic Murmurs.—A *pulmonic direct murmur* is not of very infrequent occurrence. It is heard with the first sound of the heart, at or above the base, over the pulmonary artery—namely, in the second intercostal space, near the left margin of the sternum. It is to be distinguished from an aortic direct murmur by its situation, as just stated, coupled with its non-transmission into the carotids. It represents pulmonic lesions when it is not inorganic or anæmic, as it not infrequently is. The circumstances which render it probable that it is inorganic are the same as when the question relates to the organic or inorganic character of an aortic direct murmur.

By means of the foregoing murmurs the valvular lesions are recognized and localized, but it is important to bear in mind that neither the extent nor

gravity of lesions is determined by the murmurs. Whether the direct murmurs be produced by lesions which involve obstruction or not cannot be determined by the study of the murmurs alone; and whether the regurgitant murmurs proceed from much or little regurgitation must be ascertained by other evidence than that which the murmurs afford. The intensity of the murmurs is no proof of the gravity of the lesions; slight or innocuous lesions may give rise to loud murmurs, and grave lesions may be represented by feeble murmurs. Nor does the character of the sound as regards softness, roughness, or a musical intonation furnish any definite information respecting the extent or gravity of the lesions. With reference to this important point of investigation, therefore, evidence is to be sought for elsewhere. Symptoms relating to the circulation, which have been considered under the head of the Clinical History, shed light upon this point, but in addition other physical signs are to be taken into account.

A comparison of the sounds of the heart, as produced separately at the aortic and pulmonic orifice, is one source of information. This comparison is made by listening successively to the sound as heard in the right and in the left second intercostal space near the margin of the sternum, the sound in the right side emanating from the aortic, and the sound of the left side from the pulmonic, orifice. If aortic lesions be indicated by the presence of the aortic direct or regurgitant murmur, and the lesions be of such a character that the aortic valve is impaired, the second sound, as produced by this valve, will be more or less weakened, or perhaps extinguished, and the alteration is ascertained by a comparison with the pulmonic second sound. If, on the contrary, the aortic sound be unimpaired, it may be inferred that the aortic valve is intact. A comparison of the aortic and the pulmonic sound is not less useful in the cases in which mitral lesions are shown to exist by the mitral direct or the mitral regurgitant murmur. If there be much obstruction or regurgitation, or both, at the mitral orifice, the aortic sound will be weakened by the diminished amount of blood propelled into the aorta with each ventricular systole; and if the mitral obstruction or regurgitation, or both, have led to hypertrophy of the right ventricle, the pulmonic sound will be intensified by the greater force with which the blood is propelled into the pulmonary artery by the systole of the right ventricle. Thus, by means of this application of auscultation useful information is obtained respecting the extent or gravity of the lesions, the existence and situation of which are revealed by the endocardial murmurs.

Further evidence of the extent or gravity of valvular lesions relates to enlargement of the heart. Enlargement of the heart is an effect of valvular lesions, and is proportionate to the amount and duration of the obstruction and regurgitation which the valvular lesions occasion. Hence, the degree of enlargement is a criterion of the extent and gravity of the valvular lesions. The question then arises, How are the existence and degree of enlargement of the heart to be ascertained? The altered situation of the apex, if not attributable to extrinsic causes, is evidence both of the existence and the degree of enlargement. The first effect of enlargement is to carry the apex to the left of its normal situation within the linea mammillaris. The next effect is to lower its situation to the sixth, seventh, or eighth intercostal space. In proportion as the apex is removed without the left nipple and lowered, is the amount of enlargement. The situation of the apex is to be determined by the eye or touch, or, if it can neither be seen nor felt, by finding the point where the systolic sound has its maximum of intensity. Other evidence of enlargement is obtained by percussion. The dulness within the area known as the superficial cardiac space, or the space in which the heart is uncovered of lung, is increased in degree and in extent in proportion as

the heart is enlarged. The left border of the heart is found by percussion to fall one, two, or three inches without the left nipple, the situation of the right border and the base of the heart being in most cases but little changed.

Having determined the existence of enlargement and its extent, it remains to ascertain the kind of enlargement; that is, whether hypertrophy or dilatation predominates. The most important signs in this discrimination are furnished by palpation. If either the apex-beat or additional impulses in the intercostal spaces above the apex be felt by the hand to be abnormally strong, and especially if there be a heaving elevation of the præcordia with the ventricular systole, hypertrophy predominates. The apex-beat under these circumstances may be diffused, owing to the globular form which the heart may assume when enlarged; the augmented power of the heart's action is then to be appreciated by the impulses above the apex or by the præcordial heaving. On the other hand, if dilatation predominate the cardiac impulses, if felt at all, are feeble. Auscultation also furnishes signs of importance in this discrimination. The systolic sound of the heart over the apex is loud, prolonged, and booming in proportion as hypertrophy predominates, and on the contrary the sound is short and valvular in quality if dilatation predominate. Attention to these points, in connection with the symptoms, will enable the physician to judge of the kind of enlargement to which the valvular lesions have given rise.

PROGNOSIS.—Valvular lesions not involving either obstruction or regurgitation may remain innocuous for an indefinite period. The physician should be careful not to attach undue importance to the presence of one or more of the organic murmurs. These are frequently discovered in examinations of the chest when patients complain of no symptoms referable to the heart, and in persons who suppose themselves to be in perfect health. If the lesions be accompanied by enlargement of the heart, obstruction or regurgitation, or both, may be inferred, and the lesions are not innocuous; yet so long as the enlargement is exclusively or mainly hypertrophic, serious evils directly attributable to the cardiac lesions rarely occur. The patient under these circumstances, as a rule, simply suffers more or less inconvenience. The suffering and danger, as already stated, depend chiefly on the weakness arising from predominant dilatation of one or more of the cavities of the heart. The progress of enlargement is generally slow, and it is not uncommon for patients affected with valvular lesions, together with more or less hypertrophy, to live many years, and even to old age.

The **SYMPTOMS** which denote danger, immediate or not remote, differ according to the seat of the valvular lesions. In connection with mitral obstructive and regurgitant lesions habitual and considerable dyspnoea, if referable to the cardiac affection—that is, not dependent on a coexisting affection, such as **asthma**—is evidence that the fatal termination is not very far distant. The **supervention** of general dropsy generally shows that the end is near at hand. Yet sometimes, under judicious management, the dropsy diminishes or disappears, and life is prolonged for a considerable period. Death takes place suddenly in some cases in which the valvular lesions are exclusively mitral;¹ but, as a rule, if life be not cut off by some intercurrent affection, the patient dies after a period of suffering more or less prolonged. In cases of aortic lesions involving obstruction and regurgitation, especially the latter, danger is indicated by the occurrence of paroxysms characterized by great præcordial

¹ My colleague, Prof. Janeway, has met with a case in which, a thrombus having formed in the left auricle, a portion, becoming detached, plugged the mitral orifice and caused sudden death. This was diagnosed before death.

distress and by a sense of impending death, the action of the heart being irregular or tumultuous. Sudden death is liable to occur in paroxysms of this kind, the heart being paralyzed by over-distension of the left ventricle. Sudden death sometimes occurs in cases of aortic lesions when little or no habitual inconvenience from the cardiac affection had been experienced and the existence of any affection of the heart was perhaps unknown. It is rare for lesions exclusively aortic to lead to general dropsy. The immediate or proximate danger is to be determined by the amount of obstruction or regurgitation, especially the latter, in connection with the degree of enlargement, particularly enlargement by dilatation.

In cases of tricuspid and pulmonic lesions general dropsy is an event denoting a degree of weakness of the right side of the heart from dilatation, which will be likely to lead before long to a fatal result.

In all cases of valvular lesions associated with much enlargement, especially if the enlargement be by dilatation, the prognosis is unfavorable. The patient will die sooner or later with the cardiac affection if life be not destroyed by some other disease, the occurrence of a fatal result being only a question of time and the duration varying greatly in different cases.

Death may occur in consequence of certain local affections or accidents incident to the cardiac affection. Thus, pulmonary oedema and pneumorrhagia, incident to mitral lesions, may be the immediate cause of a fatal result. Cerebral hemorrhage may be favored by dilatation of the right side of the heart and by hypertrophy of the left ventricle. The loss of blood by hemorrhage from mucous surfaces may in like manner lead to a fatal termination. The effects of emboli derived from cavities of the heart are to be included in this category.

TREATMENT.—The treatment in cases of valvular lesions has reference, *first*, to the condition of the heart as respects these lesions and coexisting enlargement; *second*, to symptoms or events incidental to the cardiac affection; and *third*, to the general condition of the patient, the condition of the blood especially claiming attention.

Valvular lesions, so long as they are either innocuous or have not led to enlargement of the heart, claim attention only with regard to preventing or retarding their progress; and for this end the strain upon the valves occasioned by the excessive action of the heart is, as far as possible, to be avoided. Very active muscular exertions, and the excitement of the circulation produced by the abuse of alcoholic stimulants and by violent mental emotions, will be likely to hasten or increase the damaging effects of the lesions. It is, however, by no means necessary to enjoin great restriction in the manner of living in these cases; it is sufficient if the habits of life be governed in all respects by prudence and moderation. It is not advisable, under these circumstances, for persons to consider themselves as invalids. If, as is frequently the case, the existence of the lesions be discovered accidentally or casually, it may not be always judicious to communicate the fact to the patient. If a medical opinion be not requested, and proper hygienic management can be secured without directing the patient's attention to the heart, much needless anxiety is sometimes spared. If, however, information be desired, it should not be withheld, but explanations may be made which will tend to prevent an over-estimate of immediate danger.

If cardiac symptoms have led the patient to apply to the physician, more or less enlargement will probably be found associated with the lesions. Let it be supposed that the enlargement which exists is mainly due to hypertrophy; it is not desirable to endeavor to diminish this hypertrophy. Inasmuch as whatever obstruction or regurgitation the lesions occasion must continue, the abnormal growth of the walls of the heart is conservative; the

comfort and safety of the patient depend upon it, and measures which tend to weaken the heart will do positive harm. On the contrary, measures to maintain the muscular tone and vigor of the heart are indicated. The diet should be nutritious. The appetite and digestion, if impaired, should be improved by tonic remedies. Moderate open-air exercise is to be encouraged, very active exertions being interdicted. In short, the object is in every way to invigorate and strengthen the system.

If dilatation predominate, the measures indicated are still those which tend to give as far as possible, tone and vigor to the heart. The labor of the circulation may be in some degree diminished by restricting the quantity of liquids ingested, redundancy of the mass of blood being in this way prevented. Especial care, however, is to be taken not to impoverish the blood. The diet is to be highly nutritious, although as dry as is compatible with comfort; tonic remedies are to be employed, and moderate exercise out of doors is still advisable. In proportion as the powers of the system are lowered the heart is weakened and dilatation favored. The object of management is, by strengthening and invigorating the system, to retard the progress of dilatation.

A recent writer upon this subject, Oertel, advocates systematic exercise, and especially mountain-climbing, as a means of increasing the muscular power of the heart.¹ There is foundation for this in both reason and experience. Quietude carried too far is perhaps likely to do more harm than over-exertion. I have known of instances in which pretty active exercise afforded notable relief from symptoms referable to valvular lesions and enlargement of the heart. In a case under my observation exercise by means of the "health-lift" was signally useful. Patients exchanging habits of activity for complete rest are likely to become rapidly worse. Extremes in either direction are to be avoided. This may be done by enjoining such an amount of exercise as can be taken without any sense of discomfort. Within that limit exercise is not only allowable but beneficial.

Thus far, the treatment has reference to the condition of the heart. Of the symptoms incident to the cardiac affection, irregularity, undue frequency, and feebleness of the heart's action call for treatment. The appropriate remedies are those which diminish the frequency, restore the rhythm, and strengthen the action of the heart. Digitalis is an invaluable remedy, regulating the heart's action without diminishing, but, on the contrary, increasing, the power of the ventricular contractions. This remedy is therefore particularly suited to cases in which the action of the heart is rendered irregular and feeble by dilatation, and it is not suited to cases in which the symptoms and signs denote hypertrophy. The fact that the diminished frequency of the heart's action is due to a lengthening of the diastole renders important a cautious use of the remedy in cases of free aortic regurgitation; yet a considerable increase of the power of the ventricular contraction may be a gain overbalancing any risk of an over-filling of the ventricular cavity from an increased diastolic rest. The pulse, the apex-beat, and the intensity of the systolic sounds of the heart, together with the subjective symptoms, enable the physician to judge of the safety and utility of the remedy in these cases. There is little ground for the traditional notion that digitalis is peculiarly a cumulative remedy, the patient being liable to a sudden manifestation of its toxic effects. This remedy is specially useful in cases of enlargement dependent on mitral regurgitant lesions. Digitalis in moderate doses (a grain or two of the leaves, two or three drachms of the infusion, from ten to fifteen minims of the tincture, or one-sixtieth of a grain of digitalin twice or thrice daily) is often well tolerated, and may be continued with advantage for a long period.

¹ Vide *Handbuch der Allgemeinen Therapie der Kreislaufs-Störungen*, Leipsic, 1884.

Not infrequently, however, after a time it causes gastric disturbance, which is sometimes avoided by changing the form of the remedy or by the addition of a carminative. Generally, it is advisable to discontinue it when its good effects have been obtained, resuming it according to circumstances.

Aconite is a useful remedy when the action of the heart is rapid, and it may be substituted for digitalis if the latter be not tolerated. It is not, however, a substitute for digitalis in respect of a tonic effect on the heart. It is specially applicable to cases in which disturbance of the heart's action is due to functional disorder superadded to lesions, and when the action is not notably weakened by dilatation.

Belladonna, as a neurotic sedative, is sometimes of service, in this respect belonging in the category of other sedatives—hyoscyamus, hydrocyanic acid, gelsemium, etc. A belladonna plaster over the præcordia has a good effect. I have known it to dilate the pupil. Nauseant sedatives, as *veratrum viride*, are not appropriate. The latter lessens the frequency, but also the strength, of the heart's action. *Nux vomica* or *strychnia* appears, either directly or indirectly, to have a tonic influence upon the heart. Caffeine is a remedy of much utility. It answers well in some cases as a substitute for digitalis. *Convallaria* and the *cactus grandiflorus* are remedies which within late years have been introduced as cardiac tonics, increasing the force and diminishing the frequency of the heart's action. They are to be regarded as succedanea of digitalis, and trial of them may be made, especially if digitalis fail or be not well tolerated. There is considerable discrepancy in the testimony of different observers respecting the value of these remedies. They are inferior to digitalis when this remedy is well tolerated. The expectations attending their introduction have not been sustained, but they are valuable in some cases, and they should not be allowed to fall into disuse.

As palliatives for cardiac dyspnoea, ammonia, the ethers, and dry cups applied to the chest are serviceable. Notable relief is obtained often by a brisk hydragogue purgative from time to time. So far from inducing weakness of the heart's action or general prostration, the effect of this measure is in these cases the reverse. Bronchorrhœa is not to be checked by opium, but small doses, administered hypodermically or otherwise, not infrequently afford relief, and are not hurtful if the patient do not suffer from the after-effects of this drug. The objections entertained by many physicians to the use of opium for the relief of cardiac dyspnoea is unfounded. If well tolerated, the effect of opium is that of a heart-tonic.

General dropsy is an event requiring treatment. Diuretic remedies should be first tried, and if these prove inoperative hydragogue cathartics are to be resorted to. Of these, elaterium is the most efficient. Given in small doses, this remedy may often be continued for a long period without producing depression. The bitartrate of potassa with jalap and podophyllin are valuable hydragogues. The Epsom salts answer exceedingly well in many cases; they are reliable, in general well tolerated, and the amount of hydragogue effect is easily regulated. If only a mild hydragogue effect be desired, the bitter waters—Pulna, Friedrichsball, and Hunyadi Janos—may suffice. In the majority of cases only partial and temporary relief of the dropsy is procured, but in some cases it is completely removed, and it may not return for a considerable period. Diuretic remedies sometimes act very efficiently. I have known the infusion of parsley-root to act with wonderful power as a diuretic remedy. If the anasarca be so extreme that the limbs become enormously distended, a great number of punctures may be made with the point of a pin, not very sharp, the punctures being so slight as not to draw blood, and through them a large amount of liquid will sometimes escape, affording for a time marked relief. Vesications or cracks in the integument

the lower limbs in some cases occur as a consequence of the distension, giving exit to an abundant flow of serum, with relief. Incisions or deep punctures are attended with a risk of gangrene. In the treatment of the dropsy, restriction of the amount of ingested liquid, as far as is compatible with comfort, is important.

A highly important part of the treatment relates to the general condition of the patient, especially to coexisting anæmia. Anæmia is not infrequently associated with the lesions under consideration, and as a consequence functional disorder of the heart is superadded to the disturbance caused by the lesions. Irregular action of the heart or excessive action, dyspnoea, and even dropsy, may be due to the superadded functional disorder. The error is not infrequently committed of attributing the symptoms in such cases exclusively to the lesions, and forming a prognosis more unfavorable than the latter actually warrant. By removing the anæmia the symptoms are relieved, and the patient may even seem to recover completely from the cardiac affection. Anæmia existing in connection with valvular lesions claims appropriate treatment—namely, removal of the cause if it be apparent; as, for example, lactation, the employment of chalybeate tonics, with nutritious diet and other hygienic measures. Exclusive of anæmia, the general condition of the patient should be improved and maintained at the highest possible point of strength and vigor. As a rule, in proportion as alimentation, digestion, assimilation, and nutrition are approximately normal, the grave effects of heart lesions are less likely to occur; in other words, the lesions are best tolerated. The importance of a nutritious diet, remedies to promote digestion if it be defective, and hygienic agencies conducive to the welfare of the body cannot be too strongly enforced as promoting tolerance and prolonging life.

CHAPTER IV.

HYPERTROPHY AND DILATATION OF THE HEART.—ATROPHY OF THE HEART.—OBESITY AND FATTY DEGENERATION OF THE HEART.—PARENCHYMATOUS DEGENERATION OF THE HEART.—NEW GROWTHS AND PARASITES IN THE HEART.—RUPTURE OF THE HEART.—THROMBOSIS OF THE HEART.—EMBOLISM OF THE PULMONARY ARTERY.

Hypertrophy and Dilatation of the Heart.

THESE conditions will be considered together, inasmuch as they are usually combined with each other. They may affect the whole heart or certain sections of it, and are therefore classified as total and partial hypertrophies and dilatations. The most important classification, however, is that based on the capacity of the heart-cavities. In *simple hypertrophy* the cavity is of normal size, in *eccentric hypertrophy* it is dilated. In *simple dilatation* the muscular wall is of normal thickness, in *hypertrophic dilatation* the wall is hypertrophied, in *atrophic dilatation* it is thinned. Hypertrophic dilatation is often employed in the same sense as eccentric hypertrophy. Rokitsansky, however, proposed to apply the term eccentric hypertrophy to enlarged hearts in which the hypertrophy predominates over the dilatation, and hypertrophic

dilatation—or, as he called it, active dilatation—to cases in which the dilatation is decidedly in excess of the hypertrophy. Of the different varieties, eccentric hypertrophy is by far the most frequently observed. Some writers have assumed the existence of a concentric hypertrophy, a condition in which the muscular wall is thickened and the cavity diminished in size. Great caution, however, is required in estimating the capacity of the ventricles after death. If the heart be found firmly contracted, its cavities seem smaller and its walls thicker than normal. It is probable that cases of supposed concentric hypertrophy are only those of firmly contracted normal or hypertrophic hearts. It is also necessary not to mistake a relaxed and flabby heart, such as is often found after death from acute infectious diseases, for a heart affected with dilatation. In so-called simple dilatation the heart is evidently hypertrophied, as the normal thickness of the muscular walls could not otherwise be preserved. In fact, hearts affected with dilatation and thinning of the walls—that is, with so-called atrophic dilatation—usually weigh more than normal, and are therefore hypertrophied. Simple hypertrophy is infrequent. It may be found in connection with certain forms of chronic Bright's disease.

In a given case it is important to determine the degree of dilatation in proportion to the hypertrophy, for while hypertrophy strengthens the muscular power of the heart, dilatation enfeebles it; the latter is therefore much the graver of the two conditions, giving rise to nearly all the symptoms.

If the enlargement be confined to the right side of the heart, the organ is increased chiefly in breadth and has a more rounded and less conical shape than normal. The rounded apex is formed by the right ventricle. When the left ventricle is hypertrophied the heart is elongated, the apex being lower down and farther to the left than normal, and if hypertrophy be combined with dilatation the septum ventriculorum is pushed over to the right side, encroaching upon the cavity of the right ventricle. If the whole heart be enlarged its shape is triangular with rounded angles. The name *cor bovinum* has, from ancient times, been applied to a heart enormously enlarged. The degree of hypertrophy varies much in different cases. The weight in the majority of hypertrophied hearts is between twelve and twenty ounces. Hope mentions one weighing forty-four ounces, and Stokes one which yielded the enormous weight of four pounds two ounces, avoirdupois. In determining a small amount of hypertrophy, it is necessary to take into consideration the variations in weight within physiological limits, as well as the age and general physique of the individual.

Hypertrophic heart-muscle is brownish-red in color, and firm, almost board-like, in consistence. The wall of an hypertrophied right ventricle has a peculiarly tough, leathery consistence. After incision the walls remain open and rigid. Both color and consistence will be modified if the hypertrophic muscle have undergone fatty degeneration, which is not infrequent.

There has been much discussion as to whether, in hypertrophy of the heart, new muscle-fibres are produced or the pre-existing muscle-fibres simply increased in volume. The formation of new muscular fibres and the proliferation of the muscular nuclei seem to be established. It is probable that enlargement of the muscular fibres also occurs, as was thought by the older writers.

Hypertrophy and dilatation of the heart are secondary affections, and consecutive in the majority of cases to some mechanical obstacle to the circulation. The obstacle may be seated in the heart itself or in the pulmonic or the systemic circulation.

The causes, seated in the heart, of hypertrophy and dilatation are—

1. Stenosis and insufficiency of the valves in front.
2. Insufficiency of the valves behind.

3. Chronic pericarditis and pericardial adhesions.
4. Myocarditis with or without partial cardiac aneurism.
5. New growths in the heart.

Weakening of the cardiac muscle from parenchymatous and from fatty degeneration leads to dilatation of its cavities.

The obstruction may be in the pulmonic circulation, in which case only the right side of the heart enlarges. The most important of these causes are—

1. Pulmonary emphysema.
2. Long-continued and large pleuritic effusions.
3. Stenosis of the pulmonary artery, either as a primary change in the artery itself or by pressure from without, as by aneurisms of the aorta, tumors, etc.
4. Curvatures of the spine, causing compression of the lungs.

Obstructions in the aortic system causing hypertrophy and dilatation are—

1. Atheroma of the aorta and larger arteries. Many cases of senile hypertrophy are referable to this cause.
2. Narrowing of the calibre of the aorta, either as a congenital condition or by pressure from without, as by tumors, etc.

It is important to notice that, contrary to former belief, aneurism of the aorta does not lead to hypertrophy of the left ventricle. This has been demonstrated by the investigations of Axel Key.¹ Aneurism of the aorta alone does not tend to increase the tension in the left ventricle. Very often, however, an atheromatous condition of the aortic valves or of the general arterial system is associated with aneurism, and this may be the cause of ventricular hypertrophy.

A well-recognized form of cardiac hypertrophy is that which is secondary to certain forms of chronic Bright's disease, particularly to the small, granular kidneys. The explanation of this is not thoroughly understood. It will be referred to under the head of Bright's Disease. Suffice it to say here that it is probably due to some resistance to the blood-current through the small vessels. This form may be simple hypertrophy, but it is usually eccentric. All of the other forms of cardiac hypertrophy are eccentric. An index to the degree of distension to which the ventricular cavity is subjected is afforded by the condition of the papillary muscles. Thus, in aortic insufficiency, which is attended with great increase of pressure in the left ventricle, the papillary muscles of this ventricle are found elongated, flattened, and in part fibrous, especially at the origin of the chordæ tendineæ; in the simple hypertrophy of Bright's disease, on the other hand, the papillary muscles are enlarged and rounded.

The name primary or idiopathic hypertrophy of the heart has been given to cases in which the disease has been attributed to habitual over-exertion of the muscular system and to repeated nervous excitation of the heart. DaCosta, Peacock, Seitz, Fraentzel, Allbutt, and others have called special attention of late years to cardiac hypertrophy and dilatation referable to over-exertion, especially in the case of soldiers who have done heavy marching in a campaign. Their observations render it probable that long-continued severe muscular strain is an important element in the production of hypertrophy and dilatation of the heart, but the infrequency with which these affections occur under the conditions named leads to the inference that an additional factor, not yet understood, enters into their causation.

The hypertrophy without valvular lesion which has been sometimes observed in cases of Graves's or Basedow's disease (exophthalmic goitre) may be referred to the prolonged frequency of the heart's action.

Hypertrophy and dilatation of the heart are sometimes found as apparently

¹ Key, *Nordiskt med. Arkiv*, Bd. 1, 1870.

idiopathic conditions when they cannot be referred to any cause. These cases are sometimes described under the name weakened heart.

The SYMPTOMS of hypertrophy are referable to the increased power of the heart's action. Hypertrophic enlargement of the left ventricle leads to an abnormal force of the current in the systemic arteries; the pulse is strong and full, the face flushed, active cerebral congestion is favored, and certain symptoms, such as pain, vertigo, tinnitus aurium, are attributable to the latter. The patient feels the powerful action of the heart, but he becomes accustomed to it, and it may occasion but little annoyance.

If the hypertrophy have been induced by an impediment to the circulation, it is conservative, as when it proceeds from valvular lesions, and is not, therefore, to be regarded as an evil. It may, however, lead or contribute to serious accidents. It is intelligible that hypertrophy of the left ventricle without valvular lesions (these being, in a measure, protective) may favor cerebral hemorrhage in cases in which the arteries of the brain have become weakened from degenerative changes. In like manner hypertrophy of the right ventricle may contribute to pulmonary hemorrhage and give rise to oedema of the lungs.

The DIAGNOSIS of hypertrophy must rest on physical signs, which are the same as when the hypertrophy is associated with valvular lesions. The fact of enlargement and its degree are determined by the altered situation of the apex-beat, together with the enlarged area of the superficial and the deep cardiac space. That the enlargement is due, either exclusively or mainly, to hypertrophy is determined by the abnormal force of the impulses of the heart, and by the prolongation, intensity, and booming character of the first sound.¹ The absence of endocardial murmurs is the basis of the conclusion that the enlargement is not connected with valvular lesions.

Hypertrophy, when conservative or compensatory, of course does not claim treatment. If it be congenital or there be sufficient grounds for considering it otherwise than conservative, measures to prevent further growth and to obviate accidents are called for. Bloodletting and other measures which impoverish the blood are not indicated. Anemia, by rendering the heart unduly excitable, involves additional inconvenience and danger. Excessive action of the heart may be moderated by tranquillizing remedies, such as aconite, hydrocyanic acid, and belladonna. In the cases of hypertrophy disconnected from valvular lesions observed by DaCosta among soldiers, marked benefit was obtained by the use of aconite, one or two drops of the tincture being given twice or thrice daily, and continued, without any increase of the dose, for months. The diet should be sufficiently nutritious, but unstimulating. Alcoholics are to be interdicted. Liquids should be taken sparingly. Active muscular exercise and emotional excitement are to be avoided.

Dilatation of the cavities of the heart may accompany hypertrophy without, as well as with, valvular lesions. If there be causes giving rise to hypertrophy which continue after the morbid growth has reached its limit, dilatation of necessity follows, and in time will become predominant; but in most cases excessive dilatation proceeds from weakness of the muscular walls, arising from fatty degeneration and other causes. The muscular walls may yield to distension and dilatation may take place when there is no abnormal impediment to the circulation; and dilatation, however induced, tends progressively to increase.

The SYMPTOMS of predominant dilatation are referable to weakness of the heart's action. This weakness is shown by feebleness of the pulse, coolness

¹ Vide preceding chapter.

and cyanosis of the surface, and if the right cavities become considerably dilated general dropsy ensues. Fatal syncope may occur from an over-accumulation of blood in the cavities in cases in which the organ is greatly enfeebled by dilatation. The physical signs show enlargement of the heart; and that the enlargement is due to predominant dilatation is shown by the feebleness of the cardiac impulses and by the weakness, shortness, and valvular quality of the first sound as heard over the apex. The absence of valvular lesions is inferred from the absence of endocardial murmur.

The indications for **TREATMENT** are the same as when the dilatation is in association with valvular lesions, the object, in general terms, being to endeavor to improve the tone and vigor of the muscular walls.

Atrophy of the Heart.

Simple wasting or atrophy of the heart is found in emaciated persons as part of the general marasmus. Diseases attended with prolonged cachexia, notably carcinoma and chronic pulmonary tuberculosis, are likely to lead to atrophy of the heart. An abnormally small size of the heart has been observed as a congenital condition in connection with imperfect development of the whole circulatory system, frequently combined with arrested sexual development. Senile marasmus may be accompanied with cardiac atrophy, but not infrequently it is associated with hypertrophy in consequence of atheroma of the large arteries. Pressure upon the heart from without, as by tumors, pericardial and pleuritic effusions, has also been adduced as a cause of atrophy. Atrophy of the left ventricle results from uncomplicated stenosis of the mitral orifice, as has been already stated. The heart may be reduced to four ounces in weight. The coronary vessels, taking no part in the atrophy, appear tortuous and prominent upon its surface. Atrophied hearts are sometimes covered with a considerable amount of adipose tissue, which may obscure the actual reduction in size of the myocardium.

Atrophy of the heart usually presents itself in the form of so-called brown atrophy. The wasted muscle has a brownish color, and under the microscope the muscular fibres are found to contain little granules of yellowish-brown pigment, accumulated especially about the nuclei. A similar pigmentation, but in less degree, is not uncommon in normal hearts.

In a clinical point of view this lesion is unimportant. It occurs under circumstances which divest it of evil consequences, if, indeed, it be not a conservative condition.

Fatty Degeneration—Obesity of the Heart.

By *obesity* of the heart (called also fatty infiltration, deposition, or growth) is understood the accumulation of adipose tissue upon the surface of the organ and between the muscular fibres. This condition is met with in corpulent subjects, and sometimes without general obesity, especially in the bodies of old persons and drunkards. The fat accumulates first in the sulci in the course of the coronary vessels, and it may eventually cover the entire right and most of the left ventricle. A moderate accumulation of fat upon the outside of the heart cannot be considered of any importance; but when the fat is excessive in amount, and especially when it penetrates deeply into the myocardium, the muscular fibres become atrophied from compression and the heart is enfeebled. It will be observed that in obesity of the heart the muscular fibres suffer only in so far as they are compressed.

In *fatty degeneration* the muscular substance is metamorphosed into fat, which appears in a granular form in the muscular fibres. By Quain's fatty

degeneration is understood this form. Fatty degeneration may attack a heart previously diseased, or the organ may have been previously healthy. In the former case the degeneration may be localized in the affected portion of the heart; in the latter instance the whole heart becomes fatty, but not of necessity in an equal degree in all parts. The fatty heart is of a pale yellowish color and is soft in consistence. The yellowish color is usually more marked in certain parts than in others. It is usually most noticeable in the inner layers of the myocardium; which are particularly liable to fatty degeneration. These layers, as seen through the endocardium, especially in the papillary muscles of the left ventricle, present a peculiar mottled appearance which is quite characteristic. The fatty degeneration may be confined to the inner part of the myocardium.

Examined under the microscope, the muscular fibres are found clouded by the presence of large numbers of granules and small globules of fat, frequently arranged in longitudinal rows within the muscular substance. The transverse striation is obscured or entirely obliterated. Some fibres are more affected than others. A small number of fatty granules is not uncommon in the cardiac muscle. When of clinical importance, the degeneration is in such amount that it can usually be recognized with the naked eye. The fatty material is undoubtedly a product of the metamorphosis of the albuminous substance of the muscle.

The parenchymatous or granular degeneration to be presently described, which accompanies many acute infectious diseases, such as typhoid, remittent, and puerperal fevers, acute yellow atrophy of the liver, etc., may be followed by a more or less extensive fatty degeneration.

Fatty degeneration of the heart, as already mentioned, is common in hypertrophied and dilated hearts, particularly during the stage of non-compensation. It may be associated with fibrous myocarditis and diseases of the coronary arteries. It is frequently present in parts adjacent to an inflamed pericardium or endocardium. General causes are important in its etiology, such as poisoning with phosphorus, arsenic, or mineral acids, and in acute infectious diseases. A most intense fatty degeneration of the heart attends certain profound anæmias, particularly pernicious anæmia and leucocythæmia.

The SYMPTOMS of fatty degeneration of the heart are due to its inability to carry on effectively the circulation. Degeneration of the left ventricle occasions feebleness of the pulse. The pulse may be irregular. It has been observed to be notably infrequent, the number of beats sometimes falling as low as 20 per minute. The infrequency of the pulse may be owing to many of the ventricular systoles being too feeble to propel the blood with sufficient momentum to be felt at the radial artery. Dyspnœa, especially on exercise, is more or less prominent as a symptom according to the feebleness with which the circulation through the pulmonary circuit takes place; and this symptom is more marked when the right ventricle is affected. Paroxysms of syncope are liable to occur, accompanied by a sense of præcordial oppression and distress. These denote distension of the cavities from an accumulation of blood. Accompanying these, paroxysms of pain referred to the præcordia, and sometimes extending to one or both upper extremities, more especially on the left side (*vide* Angina Pectoris), are not uncommon. The remarkable rhythmical irregularity of breathing known as the "Cheyne-Stokes respiration" is sometimes observed, but it is by no means diagnostic of this lesion.¹

¹ This is described by Stokes "as a form of respiratory distress consisting of a period of apparently perfect apnœa (*i. e.* absence of breathing), succeeded by feeble and short inspirations, which gradually increase in strength and depth until the respiratory act is carried to the highest pitch of which it seems capable, when the respirations, pursuing a descending scale, regularly diminish until the beginning of another apnœal period."

It occurs in uræmia, in certain cerebral affections, and in connection with other cardiac lesions. Seizures resembling apoplexy, characterized by temporary loss of consciousness without paralysis, the surface being pallid and cool and the circulation extremely feeble, have been observed in persons who have subsequently died of this affection. These pseudo-apoplectic seizures in some cases have been of frequent recurrence. These symptoms are also present in cases of fibroid degeneration or myocarditis.

The signs which accompany fatty degeneration are—feebleness or absence of cardiac impulse, and weakness of the heart-sounds, more especially the systolic sound, this sound sometimes suppressed over the apex, and if heard short and valvular like the second sound. These signs are equally present as denoting weakness of the heart from dilatation, fibroid degeneration (myocarditis), and obstruction of the coronary arteries. Sex is of some weight in the diagnosis, men being the subjects much oftener than women. The age of the patient is to be considered. Fatty degeneration rarely occurs in the male under fifty, and in the female under forty years of age. The tendency to obesity has not great weight in the diagnosis, inasmuch as fatty degeneration of the heart occurs in lean subjects as well as in those prone to corpulency. As regards the arcus senilis, clinical observation has abundantly shown that this fatty change in the cornea occurs without degeneration of the heart, and *vice versa*.

To give rise to symptoms which point to the heart as the seat of disease the fatty degeneration must be considerable. Even if considerable, it may not occasion sufficient weakness to give rise to any notable symptoms. More or less degenerative change is not infrequently found after death in cases in which it had not been suspected during life.

Causal indications are often not determinable with precision in individual cases. Clinical observation appears to show that defective nutrition is concerned in the causation. The lesion is found in those who are underfed as well as those who are overfed. General anæmia, especially pernicious anæmia, is causative. The lesion is not of frequent occurrence in connection with simple or benign anæmia. Defective nutrition of the heart from local causes is not a small proportion of cases is, intelligibly, an etiological condition. It is incident to obstruction of the coronary arteries by calcification or embolism, and to defective circulation as a consequence of impaired recoil of the aorta from atheroma or aortic insufficiency. It participates in the acute degeneration of other organs in poisoning by phosphorus, and, it is said, also by mineral acids.

The objects of treatment are to develop the muscular vigor of the heart to the extent of its capability for improvement in this respect. The diet should be nutritious, consisting of animal food in as large proportion as is compatible with the appetite and digestion. Fatty food is to be interdicted. Farinaceous and saccharine articles should form a moderate proportion of the diet. Alcohol should be taken in moderation, if at all. Moderate exercise out of doors is important; it should not be carried to the extent of overtasking the heart, but may be taken within the limits of comfort; that is, so as not to occasion hurried circulation, præcordial oppression, or dyspnœa.

The hygienic is far more important than the medicinal treatment; yet remedies may be useful. Tonic remedies are generally indicated. The appetite and digestion, if impaired, are to be improved as much as possible. If the patient be anæmic, this condition claims appropriate treatment. Coexisting disorders of any kind are to be relieved. The symptomatic effects of weakness of the heart will claim palliative measures. These measures are the same as when the weakness proceeds from dilatation.

Parenchymatous Degeneration of the Heart.

In parenchymatous as in fatty degeneration the muscular substance clouded and the striæ are more or less obscured by the presence of a granular material; but in the former the granules are albuminous, in the latter, fatty. Granular degeneration, albuminous degeneration, and cloudy swelling are synonymous terms for this affection. The name parenchymatous inflammation is sometimes used improperly in the same sense. Many of the cases formerly described as simple softening of the heart belong in this category. The degeneration affects the whole muscular substance of the heart. The heart is paler and of softer consistence than normal. The granules of parenchymatous degeneration are paler, less glistening, and usually smaller than those of fatty degeneration, from which they can be distinguished by their solubility in acetic acid and insolubility in ether. The granules are formed by some modification of the pre-existing albuminous substance, but it is not known in what this modification consists.

Parenchymatous degeneration is found chiefly after death from acute infectious diseases, such as typhus and typhoid fevers, puerperal fever, the exanthematous fevers, erysipelas, cerebro-spinal meningitis, pyæmia, and septicæmia, also in consequence of extensive burns and of poisoning by phosphorus, arsenic, etc. It can be produced artificially in animals by exposure to high temperatures, but the influence of this cause in man has been exaggerated. Severe blood-poisoning is the most efficient cause. The degeneration may develop with great rapidity. Proof of this is afforded by a case observed by Wagner,¹ who found this change in the heart and kidneys of a previously healthy girl who died six hours after extensive burns. Fatty degeneration is a frequent accompaniment and sequence of parenchymatous degeneration, but there is no necessary connection between the two processes. With doubt, parenchymatous degeneration occurs in the course of many diseases which end in recovery.

This lesion explains the weakness of the circulation out of proportion to the adynamia or general debility in certain diseases. The symptoms and signs are those which represent notable feebleness of the heart's action. As regards the signs, diminished intensity of both sounds, but especially of the first sound, characterizes the feebleness from this as well as from other lesions. These signs contraindicate depletory or debilitating measures of treatment, and, on the contrary, furnish a reason for supporting treatment in addition to the indications derived from the general condition of the system.

New Growths and Parasites in the Heart.

These have no distinctive clinical history, and therefore will receive but the briefest mention here. The most common new formations in the heart are tubercles and gummata. Miliary tubercles are frequently found in the heart in cases of acute general tuberculosis. They should be sought especially in the endocardium of the conus arteriosus of the right ventricle. Tubercles in the myocardium may give rise to myocarditis (tuberculous myocarditis). Further than this it is not known that they give rise to any symptoms. Cardiac gummata and syphilitic myocarditis have already been referred to under the head of Myocarditis. Carcinoma, sarcoma, lipoma, fibroma, myoma, myoma strio-cellulare, have been observed in the heart. Echinococcal cysts, and more rarely cysticercus cellulosæ, have been found in the heart.

The interesting subject of congenital malformations and diseases of

¹ *Handbuch des Allgem. Pathol.*, Leipzig, 1876, p. 413.

heart does not come within the scope of this work. The reader is therefore referred to works on pathological anatomy and to special treatises on the subject, including those devoted to diseases of infants, for information concerning the morbus ceruleus or blue disease, non-closure of the foramen ovale, of the ductus Botalli, of the septum ventriculorum, stenosis of the pulmonary orifice and artery, etc.

Rupture of the Heart.

The most frequent cause of spontaneous rupture of the heart is necrosis with softening of a circumscribed part of the wall. This condition, which is sometimes called myomalacia, is due to complete obstruction, either by a thrombus or an embolus, of a branch of a coronary artery. Other causes of rupture of the heart are the bursting of a cardiac aneurism or of an abscess in the heart, or the extravasation of blood resulting from rupture of a branch of a coronary artery. An ulcer of the stomach has been known to perforate the heart. Rupture of the heart very rarely happens in persons less than sixty years of age. Usually it causes instant or speedy death; but if the perforation be small it may be temporarily plugged by a clot and life continue for hours and even days. I have known death to be delayed for six hours after the symptoms denoted the occurrence of the rupture. The symptoms are those which sudden compression of the heart by the accumulation of blood in the pericardium would be expected to produce, together with the loss of blood. In most cases, however, there is no time before death for the observation of symptoms. Rupture has been repeatedly observed to occur in connection with a paroxysm of præcordial pain resembling angina pectoris.¹ In a case which came under my observation, the patient, a middle-aged man, had had repeated attacks of severe angina, and the heart gave no evidence, by physical signs, of disease. Death occurred suddenly, and a rupture was found of the left ventricle. The rupture took place within a circumscribed space in which there was advanced necrosis, the muscular wall being much softened. A branch of the left coronary artery leading to the necrosed space was completely occluded by a thrombus, and there was partial atheromatous occlusion of both coronary arteries. Except in the necrosed space the heart had not undergone fatty degeneration. [In another case, a lady about fifty years of age, under the writer's observation the heart was universally fatty, the degeneration being of the extremest type. Over the central portion of the left ventricle the muscular substance was raised into a circular aneurismal protrusion about the size of a silver half-dollar which was adherent to the parietal pericardium. The adhesions were, however, easily separable. The pericardium was distended with coagula, the blood having escaped from a small slit-like rupture of the myocardium just at the edge of the pericardial adhesion. Death was instantaneous, but had been preceded for several days by paroxysms of great dyspnoea and intense præcordial oppression.—H.]

Thrombosis of the Heart.—Embolism of the Pulmonary Artery.

It is important to distinguish ante-mortem thrombi from the coagula formed after death. At autopsies the right ventricle and auricle are usually found to contain coagulated blood. These coagula are often in great part devoid of blood-coloring matter, and they constitute the so-called decolorized post-mortem

¹For an analysis of 24 cases of spontaneous rupture of the heart by Barth, vide *Archives générales de Médecine*, Paris, 1871. For an analysis of over 100 cases by Quain, vide *The Lancet*, 1870.

clots. The blood in these cases coagulates so slowly after death that the red blood-corpuscles have time to sink; hence the upper layers of the clot consist mostly of fibrin and white blood-corpuscles, the latter being of lighter specific gravity than the red corpuscles. These post-mortem clots are yellowish-white, succulent, loosely attached to the heart-walls, and they send offshoots into the pulmonary artery and its branches. They receive the imprint of the valves and other irregularities with which they lie in contact. They have no clinical significance.

Fibrinous deposits may form in the heart during life. The usual causes of their formation are the same as those of the production of thrombi in general—namely, slowing of the circulation and alterations of the inner layer of the vessel. The presence of fibrinous deposits on the inflamed and necrotic endocardium, especially of the valves, in acute and chronic endocarditis, has already been mentioned (p. 244). Cardiac thrombi are liable to form in consequence of the slow circulation attending excessive dilatation of the heart and great weakness of the heart. These are called marantic thrombi. They form especially in the recesses of the heart, where there is a natural obstacle to the propulsion of the blood. They are to be sought, therefore, particularly in the appendices auricularum and between the columnæ carneæ, especially on the right side of the heart. They also form in cardiac aneurisms. When these thrombi attain a considerable size and project into the heart-cavities, they are often called cardiac polypi. These ante-mortem thrombi are of a whitish, yellowish, or reddish-gray color, dull in appearance, adherent to the heart-wall, often friable in consistence, laminated in structure, and with the free surface usually rounded (*végétations globuleuses* of Laennec). The central portion of the older thrombi is often broken down into a creamy mass which was formerly mistaken for pus, and such thrombi were called puriform. The creamy mass consists chiefly of granular matter. The thrombus itself is composed mostly of fibrin, blood-plates, and white blood-corpuscles, and belongs to the so-called white thrombi. Cardiac thrombi are usually small in size, but they may take up the greater part of one of the heart-cavities, and may even extend from one cavity into another. Organization of cardiac thrombi has been observed, but it is very rare.

The formation of thrombi of considerable size within the right ventricle (heart-clot) has been referred to especially in connection with acute lobar pneumonia or pneumonic fever, and also as occurring in connection with other diseases. They produce symptoms attributable to obstruction at the right side of the heart—namely, dyspnoea and cyanosis, with notable smallness and feebleness of the pulse. These symptoms develop suddenly or more or less rapidly, and are generally the forerunners of speedy death. The heart-sounds are weakened, and it may be practicable to determine that the first sound is due to the tension of the mitral valve, without the participation of the tricuspid valve. A tricuspid systolic murmur may be found which had not existed previously. Excluding pulmonary conditions which would account directly for the foregoing symptoms, and taking the latter in connection with physical signs, the diagnosis may sometimes be made with much positiveness.

Absolute rest, sustaining measures of treatment, and saturation of the blood with ammonia constitute, with our present knowledge, the measures of treatment to be pursued. The history of some cases appears to show recovery, but there is always room for doubt in these cases respecting the diagnosis.

The fibrinous deposits upon vegetations or roughened spots, occurring generally within the left ventricle, are chiefly important from their liability to

become detached and to give rise to emboli. Heart-clots of large size may form ante-mortem in the left auricle when largely dilated as a result of valvular lesions. They may also form in the left auricle when weakened by dilatation or lesion of the muscular walls.

Embolism of the main trunk of the pulmonary artery may be here noticed as a cause of sudden or rapid death. The embolus may be derived from a thrombus formed within the right ventricle or auricle, or from a thrombus formed in a large vein, most frequently the femoral vein. The symptoms are sudden, urgent dyspnoea, not explicable by physical signs, cyanosis, and coldness of the extremities, the pulse becoming rapidly small and feeble and soon extinct.

Sudden and complete obstruction of one of the primary divisions of the pulmonary artery may take place without causing death or giving rise to permanent notable inconvenience, as has been demonstrated in cases under my observation.¹

CHAPTER V.

FUNCTIONAL DISORDER OF THE HEART.—EXOPHTHALMIC GOITRE.—ANGINA PECTORIS.—THORACIC ANEURISM.

Functional Disorder.

BY the term functional disorder is meant disturbed action of the heart not dependent on either inflammation or structural lesions. The beating of the heart is sometimes abnormally intense. The patient is conscious of its violent action, as when it is temporarily excited by fear or some other strong mental emotion. This is commonly known as palpitation. The sense of violence may be a subjective symptom only, the force of the heart's action not being actually increased; but generally the action is at the same time accelerated and irregular. The irregularity is represented by the pulse, and is felt when the hand is placed over the præcordia. The patient is also painfully conscious of it; the organ appears sometimes to perform a rolling or tumbling movement, and a sensation is described as if the heart were in the throat. Intermittency of the heart's action is another feature in certain cases. The action of the heart is for an instant arrested; one, two, or three beats are lost, and generally irregularity of action precedes and follows the intermissions. Of these the patient is vividly sensible, and the feeling is that fatal suspension of the heart's action may be liable to take place. These rhythmical aberrations may be accompanied with either violent or feeble action of the heart. The varieties of functional disorder occur in paroxysms which are very variable as regards severity, frequency of occurrence, and duration.

In contrast to the above-mentioned disorders, there is an affection in which the heart beats regularly, but with great increase in frequency. The number of beats per minute may be increased to 150 or even 200. The increased frequency may persist for days, weeks, and even months. This form of disorder has been named *tachycardia* (ταχύς, καρδία). I have met with an instance of such an increase in the frequency of the heart's action,

¹ Vide *Clinical Medicine*, by the author, p. 248.

together with feebleness, that it was difficult to count the pulse, the disorder persisting for several days, accompanied by anorexia and a degree of pallor and prostration which seemed to denote impending death, recovery taking place, and examinations prior and subsequent to the attack showing no cardiac lesions.

[A remarkable example of this affection is reported by H. C. Wood.¹ The patient, an eminent medical practitioner, was at the time of Dr. Wood's publication eighty-seven years of age, and had endured the paroxysms of tachycardia for more than fifty years. They had their origin in a sharp shock or jerk produced by stepping from a piazza to the ground. The attacks frequently lasted from ten to twenty-six hours, and could at one time be invariably arrested by swallowing cold water rapidly. This remedy at last failed, and it was then discovered that the symptoms could be arrested by rapidly drinking a cup of hot strong coffee. During the height of the paroxysms the pulse rose to 160, but slight exertion, such as walking, caused it to beat at the rate of 200. The attacks have not interfered in the least with the general health or business activity. The effect of the cold and hot liquids in arresting the paroxysms is probably due, as Wood suggests, to "stimulation of the inhibitory cardiac centre produced by irritation of the peripheral nerve-filaments of the stomach."]

An occasional form of disorder is characterized by every alternate ventricular systole being so feeble as not to be appreciable by a radial pulse, the action of the heart being more or less rapid. On auscultation, the heart-sounds are found alternately loud and feeble. I have known this form of disorder to persist for several weeks. This is liable to be mistaken for reduplication of the heart-sounds, there being four sounds to each radial pulse. The error is avoided by comparing the radial with the carotid pulse. The alternate feeble systoles are always strong enough to cause an appreciable pulsation of the carotids.

Reduplication of the heart-sounds denotes a variety of functional disorder, giving rise, however, to no definite subjective symptoms and occurring in various pathological connections. Reduplication of both sounds may be appreciable, or it may be limited to one sound, which is usually the second. The reduplication is recognized easily by one accustomed to auscultation, and the proof is the occurrence of three or four sounds for each carotid pulse. A slight deviation from synchronism in the contraction of the right and the left ventricle accounts satisfactorily for the reduplication of both sounds, but not so satisfactorily for a reduplication limited to the second sound. The latter is best explained by supposing that under certain conditions of arterial pressure the recoil of the aorta and of the pulmonary artery after the ventricular systole is not in unison. This will account for a reduplication of the second sound, although the systoles of the two ventricles occur synchronously.

A variety of functional disorder to which the attention of clinical observers has not been much directed is diminished frequency of the heart's action, the condition being known technically as bradycardia. In a paper on this topic I have reported several cases in which the number of ventricular systoles was diminished to from 40 to 26 per minute.² Physical exploration in these cases showed that the disorder was not associated with any organic affection of the heart. The disorder was associated with more or less cerebral disturbance, but the evidence of intracranial inflammation, embolism, and hemorrhage was wanting, and in every instance the disorder was temporary. I have met with other examples since the publication of

¹ *Univ. Med. Mag.*, March, 1891.

² *Vide The American Practitioner*, January, 1876.

that paper. The cardiac disorder is evidently connected with some centric nervous condition which affects the heart through the inhibitory action of the pneumogastrics. To recognize the disorder as a functional one is important; otherwise it is regarded as a symptom pointing to some grave cerebral affection. It was so regarded in the cases which I have reported. (One of the most interesting of the recorded cases of bradycardia is reported by D. W. Prentiss of Washington.¹ The patient, a man aged fifty-three, "had a pulse ranging from 11 per minute to 40 per minute for over two years, being subject to frequent attacks of syncope. No disease of heart or other organ could be discovered." An autopsy was obtained, but threw no light upon the cause of the persistent slow pulse.—H.] Before deciding that the disorder exists, two points are to be ascertained—namely, *first*, that the radial beats represent accurately the ventricular systoles—that is, to distinguish this from another variety of functional disorder which has been noticed, in which every alternate systole is too feeble to produce an appreciable pulse at the wrist; and *second*, that the patient has not normally an infrequent pulse. The exclusion of grave cerebral affections by the absence of evidences of their existence other than the infrequent pulse is of course important. The cerebral affections which diminish the frequency of the heart's action rarely, if ever, occasion so great an infrequency as occurs in some instances in which it is purely functional. As great or greater infrequency is observed in some cases of fatty degeneration of the heart; hence this lesion, as well as other organic affections, is to be excluded.

Infrequency of the heart's action, reduplication of the heart-sounds, and the disorder characterized by alternate systoles too feeble to be represented by a radial pulse are rare varieties of functional disorder. The most frequent varieties are the forms of disturbance first mentioned—namely, rapid action either violent or fluttering, irregularity, and intermittency, occurring in paroxysms. They are often met with in practice. They usually give rise to great mental apprehension. The patient has a firm conviction of the existence of organic disease and is in fear of sudden death. It is sometimes difficult to remove this conviction by the most positive assurances to the contrary. Cases of functional disorder are distinguished, as a rule, by much mental anxiety and depression, in this respect differing from cases in which disturbed action is due to structural lesions.

The causes of functional disorder are various. It sometimes occurs in so-called full-blooded persons addicted to the pleasures of the table, digesting and assimilating readily, and taking but little active exercise. It is much oftener, however, associated with anæmia. Anæmic persons are rarely exempt from more or less disturbance of the heart's action. It may be produced by long-continued mental anxiety or depression. It frequently occurs in persons of an anxious, worrying disposition, and in those who are constitutionally disposed to melancholy. The effect which it produces on the mind reacts on the disorder and tends to perpetuate it. It appears in some cases to be dependent on indigestion or dyspepsia, and paroxysms are often excited by dietetic errors. The immoderate use of tobacco or of strong tea and coffee gives rise to it in some persons. It is incidental to the gouty diathesis. The exhaustion following prolonged mental excitement and physical exertions may be accompanied by it. It prevailed to a great extent among soldiers during the late civil war, excessive and persistent palpitation often leading to discharge on the ground of disability from supposed organic disease of the heart. Excessive venery and habits of self-abuse are to be included among the causes. The associated symptoms will of course vary according to the different circumstances under which it occurs. The differ-

¹ *Trans. Ass. Am. Phys.*, vol. vi., 1891.

ent causes of course act upon the nervous system; but it is not certain whether the particular nerves acted upon be the pneumogastrics, the sympathetic, or the nerves and ganglion-cells in the substance of the heart. A predisposition seems to enter into the etiology. Some persons apparently have, as an idiosyncrasy, an irritable heart, and they generally have other evidences of what is called a nervous temperament.

It is extremely desirable, in view of the comfort and welfare of the patient, to determine with positiveness, in cases of functional disorder, that structural lesions do not exist. Several points connected with the history and symptoms have a bearing on the diagnosis. The occurrence of the disturbance in paroxysms, the action at other times being regular; the paroxysms occurring at night rather than in the daytime, and frequently not being occasioned by any obvious cause, such as muscular exertion or mental excitement; the ability of the patient to take active exercise without palpitation or dyspnoea when not suffering from the disorder; and the intensity of mental anxiety and apprehension,—are points which render it probable that the difficulty is purely functional. These points, however, are not conclusive. A positive diagnosis is to be based on the exclusion of lesions of structure, by the absence of the physical signs of the latter. If, on a careful examination of the chest, the heart be found not to be enlarged; if there be no murmur present or if an existing murmur be inorganic; if the heart-sounds be normal; and if, from the absence of persistent weakness or irregularity of the heart's action, fibroid or fatty degeneration of the heart and obstruction of the coronary arteries can be excluded,—the affection may be confidently pronounced functional. Without the negative proof afforded by physical exploration the mind of the practitioner must be in doubt as to the diagnosis. If he give a decided opinion, it is a guess which may prove to be either right or wrong. If he avoid giving a decided opinion, the inference which the patient usually draws is that organic disease exists and that the physician is reluctant to tell the truth. I could cite, from cases which have come under my observation, not a few in which patients were for many years rendered unhappy and deterred from engaging in the active duties of life, either by an erroneous medical opinion that they had organic disease of the heart or by a fixed belief that such was the fact, based on the indecision of the physician.

The curative treatment of functional disorder must have reference to the circumstances with which it is connected. Occurring in connection with what is known as a "full habit," the measures indicated are—restriction of diet, exercise in the open air, with depletion by saline laxatives and perhaps by small bloodlettings. Occurring in connection with anæmia, measures of precisely an opposite character are indicated—namely, those designed to restore the normal condition of the blood. An investigation with reference to the source of the disorder is to be made in all cases, and the causes, if apparent, are to be removed. If connected with dyspeptic ailments, these are to be remedied by appropriate treatment; and if dependent on the gouty diathesis, this will claim suitable remedies. In the great majority of cases the proper treatment consists of tonic remedies, a nutritious diet, and an avoidance of excesses of all kinds; a proper amount of sleep; the interdiction of tobacco, strong coffee, and tea; and out-door life with mental recreation; in short, an invigorating system of hygiene. Positive assurances of the absence of organic disease, such as may be given if based on the absence of all the physical signs of lesions, will often go far toward effecting a cure, the disorder being frequently kept up by mental disquietude occasioned by the fear of sudden death.

During the paroxysms palliative measures are called for. These consist of ethereal stimulants, antispasmodics, and occasionally opiates, with sinapisms

or stimulating liniments to the chest. If paroxysms occur frequently a belladonna plaster may be constantly worn over the præcordia. Blisters or other severe counter-irritants are never requisite. Small doses of aconite are useful if the action of the heart be violent, and, on the other hand, if the action be feeble and irregular digitalis may prove of use. Kunze and other German authors recommend as a palliative measure wearing an ice-bag over the præcordia. A mouthful of brandy or some other spirit, swallowed undiluted, will sometimes promptly arrest a paroxysm.

Persons who are strongly predisposed to disturbed action of the heart are liable to suffer more or less from paroxysms of functional disorder for many years or during their whole lives. The mental anxiety in such cases after a time ceases, and patients become reconciled to this as to other physical evils. The frequent recurrence of functional disorder for an indefinite period does not lead to the development of organic disease. The physician is fully warranted in giving positive assurance to the patient on this point.

In the foregoing remarks on functional disorder it has been assumed that structural lesions are not present; but functional disorder and lesions may be associated when the former is not dependent on the latter; in other words, the causes which give rise to functional disorder when the heart is free from lesions will produce the same effect when cardiac lesions exist. It is highly important that the practitioner appreciate this fact. Not infrequently the disturbance of the heart's action in cases in which organic murmurs are found is mainly or exclusively functional. It is not uncommon for practitioners to err in considering all the symptoms referable to the heart as arising from organic lesions, although these may be entirely innocuous. Anæmia coexisting with lesions may occasion greatly disturbed action of the heart, with dyspnoea and even general dropsy, so that the patient may seem to be in the last stage of cardiac disease, and if the anæmia be cured the recovery sometimes appears to be complete. It should always, therefore, be a question in cases of organic lesions whether more or less of the symptomatic phenomena may not be due to functional disorder arising from anæmia, deranged digestion, or a morbid condition of the nervous system produced by tobacco, coffee or tea, mental depression, excessive venery, or gout. This question is to be decided in the affirmative when causes of functional disorder are discoverable, and when the organic affection, as determined by the physical signs, appears to be insufficient to account for the symptomatic phenomena. In proportion as the latter are fairly attributable to functional disorder, the prognosis is of course less grave, and improvement may be expected from appropriate treatment.

Enlargement of the Thyroid Body and Prominence of the Eyeballs (*Exophthalmic Goitre*), associated with Functional Disorder of the Heart.

Within recent years the attention of clinical observers has been directed to an affection characterized by enlargement of the thyroid body and prominence of the eyeballs, conjoined with inordinate action of the heart. These three pathological events form a striking combination, giving to the affection a well-marked individuality. In the absence of a name expressive of its character, a German author, Hirsch, applied to it the name *Basedow's disease*, after a German observer who was among the first to describe it fully; and the distinguished clinical teacher, Trousseau, in view of the prior claim of the late Dr. Graves, proposed to call it *Graves's disease*. The three events just named evidently have some pathological connection, the nature of which is not yet fully established.

The prominence of the eyes is the most remarkable of the triple events. Existing in some cases in a marked degree, it gives to the countenance a peculiar expression. The projection of the globes displays more or less of the tunica albuginea, and the patient has a ferocious, staring look, which, existing in both eyes, is at once diagnostic. The projection is sometimes so great as to prevent closure of the lids, and the eyeballs are partially exposed during sleep. Vision is generally not impaired, and the appearance of the eyes, aside from the prominence, is natural. The condition of the eyes does not involve pain, but the patient sometimes feels as if the eyeballs were being squeezed out of the sockets. Accompanying and sometimes preceding the exophthalmus defective co-ordination of the movements of the eyeballs with those of the upper eyelids is observed. If the patient look downward, the eyeballs move without corresponding movements of the lids. This defective co-ordination is not a feature in all cases. The exophthalmus is sometimes more marked on one side, and it may be unilateral. Falling out of the eyebrows and cilia is sometimes observed. The thyroid body is more or less enlarged, the enlargement being usually greater on the right side. The increase does not go on indefinitely, forming the immense tumors which are sometimes seen in cases of ordinary bronchocele, or goitre, but ceases after a moderate or considerable augmentation of bulk has been attained. The swelling does not give rise to pain, but it may occasion some obstruction to respiration from pressure on the trachea, and may lead to embarrassed breathing and modification of the voice by interfering with the function of the recurrent laryngeal nerve. The thyroid arteries are enlarged, and a strong pulsation is felt over these and the carotids, frequently accompanied by marked thrill. Arterial and venous murmurs, frequently loud and sometimes musical, are heard when the stethoscope is placed over and near the enlarged thyroid body. The degree of the thyroid enlargement is often variable at different times.

Increased frequency of the heart's beats (tachycardia) is a constant and notable feature. In some cases this amounts to a persisting palpitation. The pulse varies from 100 to 140 beats per minute. Valvular lesions and enlargement of the heart exist in some, but by no means in all cases. When present, they do not account for the functional disorder. Loud inorganic murmurs at the arterial orifices of the heart are not infrequent. The inordinate action of the heart may continue persistently for months and years. [Tremor is a symptom of Graves' disease to which attention was first called by Charcot. It may be continuous or intermittent, universal or involving but a single extremity. It has been studied in detail by Marie, who finds that it presents features distinguishing it from all other forms of tremor. The chief of these are its rapidity and the regularity of its graphic representation. The to-and-fro movements of Graves' disease occur at the rate of 8 to 9½ per second, whereas the tremors of paralysis agitans, of general paresis, of alcoholism, and of senility are much slower (about 4 to 5 per second) and more irregular. This symptom is considered so important by Marie that he believes the diagnosis of Graves' disease to be justified by its presence in association with tachycardia. Vigouroux has called attention to the fact that the electrical resistance of the skin is diminished in this disease. This is probably attributable to the abnormal amount of fluid in the dilated cutaneous vessels.—H.]

More or less anæmia coexists generally, but not invariably. This has been by some incorrectly considered as an essential pathological element of the affection. The anæmia, however, is usually marked. [Certain anomalies of secretion, such as hyperidrosis, sometimes unilateral, excessive lachrymation, salivation, diabetes insipidus, and even glycosuria, have often been observed

in the course of Graves' disease. Trophic disturbances of the surface of the body are also by no means rare. Among them are sclerema and bronzing of the skin, gangrene of the lower extremities, and circumscribed loss of hair—alopecia areata.

Other signs of disturbed innervation are hemicrania, trifacial neuralgia, hemianæsthesia, chorea, and paralysis. The latter is most apt to affect one or more of the cranial nerves, although the extremities are sometimes involved. Progressive muscular atrophy and muscular pseudo-hypertrophy have also been observed.—H.] Other symptoms are mental depression and irritability, insomnia, amenorrhœa, abnormal increase of the appetite followed by anorexia, hysterical phenomena, and emaciation. The affection is essentially chronic. In the majority of cases it continues for years. It does not tend intrinsically to a fatal result, but patients are liable to be cut off during its continuance by some intercurrent affection. [Sudden death with cerebral symptoms is a possible termination. In a case recently seen by the writer at the Woman's Hospital of Philadelphia, delirium suddenly supervened, and the patient died in a few hours in a state of profound coma. There was no disease of kidneys, nor, in fact, any demonstrable morbid condition except the so-called Graves' disease, the three cardinal symptoms of which were well pronounced. A similar case, made memorable by the fact that the patient was of the male sex, was under the writer's care at the Philadelphia Hospital several years ago.—H.] Recovery takes place in a certain proportion of cases, the improvement being slow, and some degree of enlargement of the thyroid body and prominence of the eyes often being permanent. Fothergill quotes from Von Dusch 14 complete recoveries in 56, and great improvement in 26 cases; and of cases observed by Von Graefe, the ratio of recoveries was 20 per cent., and of great improvement, 30.

The pathological character of the affection is not established. That the three pathological events are due exclusively to anæmia is disproved by the occurrence of anæmia so frequently without these events, and by the fact that there is not always coexisting anæmia. The enlargement of the thyroid body is chiefly due to enlarged vessels. The prominence of the eyes is not due to enlargement of the globes. In some autopsical examinations which have been reported an abnormal amount of areolar and adipose tissue has been found at the bottom of the orbit; but that the protrusion is not chiefly due to this cause is shown by the fact that it has been observed to cease after death, and during life moderate pressure suffices to restore the globes to their normal situation. Enlargement of the vessels behind the globes is probably the chief cause. The prominence of the eyes and enlargement of the thyroid body are consecutive to the cardiac disorder. Cases are observed in which enlargement of the thyroid body is conjoined with inordinate functional activity of the heart, without prominence of the eyes, and the two latter may be associated without enlargement of the thyroid body. Examples of each of these variations have fallen under my observation. I have met with cases of rapid action of the heart persisting for a long period without either prominence of the eyes or enlargement of the thyroid bodies, in which I suppose the affection to be the same minus these associated events. Considering that the cardiac disturbance always precedes the two other characteristic events, that either of the latter may be wanting, and that both involve enlargement of vessels, a fundamental morbid condition evidently relates to the circulatory system; but this condition probably involves a prior neuropathic affection which, it is probable, pertains to the sympathetic nerve. In some instances morbid appearances after death in and around the cervical sympathetic nerve have been found, but in other instances nothing was discoverable. The neuropathic condition is supposed by some to be seated

in either the cervical portion of the spinal cord or the medulla oblongata. The affection in the great majority of cases occurs in females. Of 50 cases collected by Wilthuisen, a Danish author, only 8 were male subjects. In all the cases which I have seen, save one, the patients were females. The disease sometimes shows an hereditary tendency.

The indications for treatment relate to the functional disorder of the heart together with the morbid state of the nervous system and the often-coexisting anæmia. Sedative remedies which tranquillize the action of the heart without producing depression or interfering with the appetite and digestion are indicated. For this end, hydrocyanic acid, aconite, belladonna, and digitalis may be employed. The anæmia calls for tonic remedies, especially ferruginous tonics; and the latter have seemed to be beneficial in cases where they have been observed. Arsenic has been found useful, but in some instances it has recently done harm. Iodine, with reference to the affection of the thyroid gland, is of doubtful utility. In two cases under my observation, recovery in the first case and notable improvement in the other case occurred under the use of the tincture of aconite. In the first of these cases the patient took one minim only of the tincture three times daily, but continued it for three years in conjunction with a chalybeate tonic. At the end of that period she was perfectly well and had increased in weight forty pounds. In the other case the dose of the tincture was gradually increased to seven minims three times daily, and was continued steadily for ten months without a chalybeate, and the anæmia not existing in this case. Several observers bear testimony to the usefulness of galvanization, with the constant current, of the cervical sympathetic nerve. Cases of recovery under this agent have been reported. Ergot is among the remedies which have been found of service. Hygienic measures are of great importance. Freedom from mental depression is to be secured as far as possible, and, whenever practicable, change of scene and other means of mental recreation are advisable. The diet should be nutritious, and out-door life is desirable. Trousseau advocated the employment of cold water after the hydropathic method. [W. H. Thomson of New York recently reported success from the treatment of Graves' disease with fermented milk ("matzoo"), his method being based upon its supposed relation to digestive disorders. In addition, he administers an occasional mercurial laxative and intestinal antiseptics such as salol, bismuth subcarbonate, and naphthalin.—H.]

Angina Pectoris.

The affection known as angina pectoris involves, as an essential feature, neuralgia, and might therefore be included among the diseases of the nervous system. It is considered here on account of its frequent connection with cardiac lesions and with notable disorder of the heart's action. The following description will relate to typical cases of angina associated with disorder of the heart.

The affection is characterized by pain, usually intense, burning, tearing, lancinating in character, emanating from the præcordia or beneath the sternum, and radiating thence in different directions—namely, into both sides of the chest, the back, and frequently the left shoulder; extending down the arm and sometimes to the forearm; occasionally felt in the forearm and hand and not in the shoulder and arm; in some cases extending more or less to both upper extremities, and it has been known to extend into one or both of the lower extremities; and, finally, it may shoot upward into the neck, temples, and jaws. Different cases differ much as regards the intensity of pain and the situations, among those just named, in which it is felt. The pain in some cases is so intense as to be truly excruciating, and is accom-

nied by a feeling of constriction of the chest; in other cases it is moderate or even comparatively slight.

The affection is paroxysmal, and the pain is but one of the elements which enter into the paroxysm. The action of the heart is generally more or less disturbed. The beats are irregular, sometimes violent or tumultuous and sometimes feeble. In some cases the pulse is notably slow. An indescribable anguish or "heart-pang" is another element. A vivid sense of impending death is felt. The paroxysm is usually developed suddenly, and the patient feels compelled instantly to remain perfectly still, seizing hold of some firm support in order to maintain a fixed position. The patient is afraid to breathe freely, although the power of doing so is not lost. Dyspnoea does not belong to the paroxysms, save in so far as it may depend on existing cardiac lesions or on the voluntary restraint of the respiratory movements. A sense of numbness is felt in the parts into which the pain extends. The countenance denotes anxiety and suffering. The surface is generally pallid, cool or cold, frequently bathed in perspiration, and sometimes cyanosed or livid.

Cases differ greatly as regards not only the severity of the paroxysms, but their duration and the frequency of their recurrence. They usually last for a few moments only, but in some cases they continue for several hours. They may recur at wide intervals or frequently. As a rule to which there are a few exceptions, if a paroxysm have been once experienced other paroxysms will follow sooner or later. Generally they become progressively more and more frequent. At first and for some time they appear to be excited by some notable cause, such as unusual muscular exertion or mental emotion, but after a time they are liable to occur from trivial causes and without any apparent cause. They are sometimes produced during sleep, apparently by distressing dreams.

The affection as thus described is incident generally to organic disease of the heart, of the aorta, or of the coronary arteries, but, as far as at present known, not to any one form of lesion. It is much oftener associated with lesions at the aortic than at the mitral orifice, yet it occurs in only a very small proportion of the cases of aortic lesions. It occurs in some cases of fatty degeneration of the heart and of myocarditis without valvular lesions. It is sometimes associated with aneurism of the aorta. The affection is rare. Of over 150 cases of organic disease of the heart which I analyzed in 1859, it occurred in only 7, and it occurred in 8 out of 188 additional cases analyzed in 1869. That it has a pathological connection with organic disease of the heart is certain; but upon what particular condition or circumstance common to different forms of organic disease it depends is not ascertained.

Angina pectoris, especially if associated with diseases of the heart, involves liability to sudden death. Death takes place suddenly in a paroxysm. The most reasonable way of accounting for the sudden death, as it seems to me, is to attribute it to over-accumulation of blood within the ventricular cavities, and arrest of the heart's action as a result of paralysis from distension. The explanation, in fact, is the same as of sudden death in cases of free aortic regurgitation and fatty degeneration. The liability to sudden death characterizes cases in which the coexisting organic disease is of a kind to favor sudden over-accumulation of blood in the cavities. Aortic lesions and fibroid or fatty degeneration have this effect. If the lesions do not lead to this effect, patients rarely die suddenly, but linger on for an indefinite period, with the recurrence of the paroxysms more or less frequently. Moreover, the overloading of the cavities of the heart will account for elements of the paroxysms other than the pain—namely, the disturbed action of the heart, the indescribable anguish, and the sense of impending death. If the lesions to which the angina is incident be not of a character to lead to overloading and conse-

quent distension of the ventricular walls, the suffering is mainly from the pain. Some cases of angina are of this description, very little disturbance of the heart's action accompanying the paroxysm. On the other hand, all the elements of a paroxysm of angina, except the pain, are observed not infrequently in cases of aortic lesions with regurgitation or with fibroid or fatty degeneration; and sudden death is liable to occur in the paroxysms of distress to which patients affected with these lesions are subject, the paroxysm lacking only pain to constitute angina pectoris. The prognosis in cases of angina is always grave if physical signs show the existence of serious cardiac lesions; and sudden death is to be expected if there be much aortic regurgitation, or the habitual weakness of the heart render probable impaired nutrition of the organ from obstruction of the coronary arteries or degeneration of the walls. The danger, it is to be observed, is not to be measured by the intensity of the pain; it is not the pain which kills, but the coexisting organic disease.

Angina pectoris, as far as the neuralgic element is concerned, may occur without any evidence of coexisting disease of the heart or the aorta. Several examples have fallen under my observation. In these cases the paroxysms generally lack those elements which are derived from cardiac lesions. The necessity of keeping a fixed posture while the paroxysm lasts is not felt in the same degree; and the patient may writhe with pain and try frequent changes of posture with the hope of obtaining relief. The sense of impending death is less or may be wanting. There is less danger of sudden death, and the prognosis as regards recovery is favorable. These points are to be considered in the differentiation of these cases from those in which the angina is connected with disease of the heart; but the absence of cardiac lesions is determined by the negative result of a careful physical exploration of the chest. It is, however, to be considered that there are anatomical changes not represented by physical signs—*e. g.* defective nutrition from obstruction of the coronary arteries. It may be stated that the danger in a given paroxysm is in proportion to the feebleness and irregularity of the heart's action, together with a feeling of impending dissolution. In the endeavor to estimate the danger, the nature and extent of lesions, as evidenced by signs, are to be taken into account. Much damage of the aortic valves, dilatation of the left ventricle, and weakness of the heart from fatty or fibroid degeneration are the conditions which especially render paroxysms dangerous. Yet there are cases in which the paroxysms recur for a long time without proving fatal, although heart lesions exist, and if the latter do not exist it is probably true that there is little danger of sudden death. I have reported several instances of recovery in the second edition of my work on *Diseases of the Heart* (1869). Such instances should not be lost sight of in the prognosis.

Angina is to be discriminated from intercostal neuralgia and gastralgia. Each of these affections I have known to be mistaken for it. Paroxysms of intercostal neuralgia are sometimes so severe as to rival, in the intensity of pain, attacks of angina. In other respects the points of distinction are sufficiently marked. Both intercostal neuralgia and gastralgia are distinguished by their own diagnostic traits, aside from the absence of those which belong to angina. This statement applies also to paroxysms of pain caused by the passage of gall-stones. The most rational explanation of the immediate cause of the paroxysms is that they are due to deficiency of arterial blood in the walls of the heart (ischæmia).

Pertaining to the pathological character and relations of the different elements in angina are discussions which cannot be here entered into. The neuralgic element probably has its primary seat in the cardiac plexuses, and the radiation of pain to the neck and upper extremities, as well as to other parts of the chest, may be explained by anatomical connections with branches of the

cervical and dorsal nerves. As remarked by Eulenburg, the pain closely resembles that referable to the sympathetic nerve in other situations; for example, hepatic colic, enteralgia, etc. The disturbed action of the heart, irrespective of cardiac lesions, is as unintelligible as when it occurs in the various forms of functional disorder. To institute several varieties of the disease according to the different nerves supposed to be involved seems to me to be, in the present state of our knowledge, premature and confusing. Practically, however, the presence or absence of cardiac lesions and the degree of disturbance of the heart's action in the paroxysms are important points, especially in reference to prognosis and the liability to sudden death.

The TREATMENT embraces measures to afford relief in the paroxysms and those indicated in the intervals. The palliative measures embrace opium, given promptly and sufficiently to relieve the pain. It should be given in a form to act as speedily as possible. The hypodermic method, if the physician happen to be at hand, is to be preferred. Alcoholic, ethereal, and other stimulants are indicated in proportion as the action of the heart is irregular and feeble. Revulsive applications to the chest and extremities are appropriate. Swallowing pieces of ice has been found effective. The nitrite of amyl is a valuable remedy. Five drops inhaled from a handkerchief held over the nostrils will often almost instantly arrest a paroxysm. It may prevent sudden death, and trial of it should therefore always be made, observing, of course, proper precautions in its use. The remedy is efficacious in only a certain proportion of cases. Naturally, its efficacy is most marked when there is much arterial tension, but it may relieve, although this element be wanting, by diminishing the accumulation of blood in the heart-cavities. The inhalation of ether or of chloroform is to be mentioned among the resources for arresting the pain or mitigating its severity. The inhalation of chloroform should not be resorted to if the action of the heart be feeble.

In the intervals the patient should avoid, as far as possible, everything which will be likely to provoke a paroxysm, such as active exercise, mental excitement, over-ingestion of food, and the abuse of alcohol. Aside from prophylaxis, the measures indicated are those which have reference to the causes of neuralgia, to the general health, and in the majority of cases to coexisting organic disease of the heart or the aorta. Anstie found arsenic, in small doses long continued, extremely useful in preventing the paroxysms. Others have recommended this remedy, and, again, others have seen no benefit from it. A fair inference is that it is sometimes useful and sometimes not, as in other neuralgic affections. [Nitro-glycerin and iodide of potassium are valuable remedies in this disease, and with proper precautions they may be administered continuously for almost indefinite periods. In a case at the Philadelphia Hospital, in which, with aortic stenosis and insufficiency, there were daily attacks of angina of severest type, complete relief was obtained by the use of small doses of tincture of aconite (gtt. ij every four hours). After six weeks of freedom from pain the aconite was stopped, and in a day or two the paroxysms of angina recurred. On resuming the aconite they again ceased.—H.] Trousseau, who regarded the affection as analogous to epileptic seizures and called it *cardiac epilepsy*, advised the long-continued employment of belladonna. Electrization of the surface within the præcordia has been found useful both in arresting the paroxysms and postponing their occurrence. The cases most likely to be amenable to treatment are those in which the angina is purely neuralgic—that is, not associated with heart lesions.

The name angina is singularly inappropriate as applied to this disease, inasmuch as neither the symptoms nor the danger have aught to do with

strangulation. The term stenocardia has significance only as denoting a sensation accompanying the pain. Of the other various names, most imply erroneous views of the nature of the malady. Cardialgia would be an appropriate name had it not been applied to a gastric affection.

Thoracic Aneurism.

An atheromatous condition of the arteries has been usually assigned as the leading cause of spontaneous aneurisms. This atheromatous process is at the onset inflammatory; it is an endarteritis chronica deformans (Virchow). The intima at first is swollen and of a whitish or gelatinous appearance in patches. In these swollen patches are round, fusiform, and stellate cells in increased number. The intercellular substance is imperfectly fibrillated. The endothelial lining of the vessel is preserved. Subsequently, necrosis with fatty and calcareous degenerations occurs in the cells and intercellular substance; and to the resulting pulpy mass, often containing cholesterol, the name atheromatous abscess has been inappropriately applied. This mass may be discharged by rupture of the endothelial covering, and an atheromatous ulcer is the result.

Recent investigations have rendered it probable that undue importance has been assigned to atheroma as a cause of aneurism. Atheroma is most frequent in old age, a period of life in which aneurisms are by no means most common. The view is now held that the most frequent cause of spontaneous sacculated aneurisms is to be sought in changes in the middle or muscular coat of an artery. It is this coat which normally gives the greatest strength to the arterial wall. The changes in the middle coat which lead to aneurism are various. A rupture of the elastic and of the muscular fibres in a previously healthy, or more frequently in a diseased, middle coat may be the result of traumatism or of some severe strain. A frequent change in the media, especially in cases of atheroma, is a localized inflammation, characterized at first by an accumulation of lymphoid cells, and later by a growth of fibrous tissue. This mesarteritis, as the inflammation is called, leads to a weakening of the middle coat and consequent production of aneurism.

The ascending aorta is the most frequent seat of large aneurisms. If, however, small or miliary aneurisms be reckoned, then the cerebral and the pulmonary arteries are most frequently affected.

Thoracic aneurism occurs either in the form of a diffuse dilatation, most frequently of the ascending aorta, or in the sacculated form. It is the sacculated aneurism which is specially considered in the present article.

According to Rindfleisch, aneurisms of the ascending portion and of the arch of the aorta develop most frequently in the course of a spiral line which corresponds to the places against which the blood impinges with greatest pressure. This line begins on the anterior aspect of the bulb of the aorta, gradually passes on the front of the ascending aorta toward the right, crosses the convexity of the artery just before the innominate trunk is given off, and from here passes very gradually to the posterior and internal aspect of the descending aorta.

Referring the reader to other works for a fuller account of aneurisms as regards their pathology and morbid anatomy, I shall consider in this article aneurismal tumors of the thoracic aorta with reference to their symptoms, physical signs, prognosis, and treatment. As bearing on the diagnosis, it may be here stated that aortic aneurism is a rare event under forty years of age, and that syphilis is often a remote cause.

Aneurismal tumors may spring from the thoracic aorta at different points. Not infrequently they originate within the pericardium, in the sinuses of

Valsalva, and in this situation rupture occurs before the tumor attains to great size, the hemorrhage taking place into the pericardial sac, and of course causing instant or very speedy death. A fatal result from aneurism in this situation may occur without having been preceded by any symptoms of importance; death takes place unexpectedly, perhaps when the health was apparently perfect. The diagnosis is difficult and perhaps impossible. Of 703 cases analyzed by Sibson,¹ 87 were within the pericardium. The ascending portion of the arch beyond the pericardium is the most frequent site. In 193 of the 703 cases analyzed by Sibson the situation was in this portion. The ascending and transverse portions are not infrequently both involved in the dilatation. This was the case in 140 of 703 cases. The transverse portion was affected alone in 120 cases, and conjointly with the descending aorta in 20 cases. The descending portion of the arch was the seat in 72, and the aorta below the arch in 71 cases. The aneurismal tumors in the larger proportion of cases spring from the outer aspect of the artery, but they may spring from either the inner, posterior, or anterior aspect.

Aneurismal tumors, according to their situation and size, give rise to certain symptoms and signs by pressing upon the different surrounding parts. Unless referred to their true source, these symptoms may mislead the physician by appearing to indicate other affections; and by means of these symptoms and signs not only may aneurism be suspected, but, assuming its existence, its situation may be inferred.

Interruption of the circulation through the innominate and the left carotid and subclavian artery may arise either from the pressure of the tumor on these vessels or obstruction by fibrinous plugs. Feebleness or extinction of the pulse in the radial, brachial, or carotid artery on one side is one of the symptoms of aneurism, and indicates its situation to be at the right or left extremity of the transverse portion of the arch. When the radial pulse is not abolished, but more or less weakened, the contrast between the pulse of the two arms is well shown by a comparison of the visible characters as traced by the sphygmograph. A notable retardation of arterial pulsations beyond the seat of the aneurism is sometimes observed. Thus, when the aneurism is seated between the points of origin of the great vessels of the arch of the aorta, the radial pulse is felt later on one side than on the other, and if the aneurism be seated in the descending aorta the pulsations of the arteries below occur later than the pulse at the wrist. An aneurismal tumor springing from the ascending or transverse portion of the arch may press upon the superior vena cava or the venæ innominatæ, and induce venous congestion limited to the head and upper extremities or to one upper extremity, accompanied, perhaps, by more or less œdema. These symptoms point to the existence of aneurism and its situation.

An aneurism seated in the transverse portion of the arch may press upon the trachea or one of the primary bronchi and interfere with respiration. If the obstruction of the trachea be considerable, the breathing is labored, and may be accompanied with a noise, heard at a distance, called stridor. Auscultation will show feebleness of the respiratory murmur on both sides of the chest if the trachea be pressed upon, but feebleness limited to one side and the murmur exaggerated on the other side if one of the bronchi be obstructed. Embarrassment of respiration may proceed from pressure upon the recurrent laryngeal nerve. If the pressure be sufficient to interrupt the function of the nerve on one side, laryngeal obstruction arises from an arrest of the respiratory movements of the glottis on that side. The embarrassment from this cause, however, is not great. The laryngoscope in these cases shows the vocal cord on one side to be paralyzed, while the respiratory movements of

THE HEART IN

The diagnosis of the heart in the related of the patient's history and physical examination is a difficult task. The history of the patient's symptoms, the physical examination, and the results of the various tests are all factors which must be considered in the diagnosis of the heart. The history of the patient's symptoms is the first step in the diagnosis of the heart. The physical examination is the second step. The results of the various tests are the third step.

The history of the patient's symptoms is the first step in the diagnosis of the heart. The physical examination is the second step. The results of the various tests are the third step. is highly diagnostic. This sign, first described by Porter, has been carefully studied by MacDonnell and Ross of Montreal.—H.]

The PROGNOSIS in cases of thoracic aneurism relates chiefly to the duration of life. The instances of recovery are few. In the majority of cases death is the result of rupture of the aneurismal sac. The rupture may take place in various directions—namely, externally, or into the œsophagus, trachea, bronchi, pleural cavity, heart, venæ cavæ, spinal canal, pericardial cavity, etc. The rupture may be at first small, so that death takes place more or less gradually, or it may be large enough to cause a sufficient hemorrhage to destroy life within a few moments. I have met with a case in which, after a considerable hemorrhage caused by rupture into a bronchus, the opening closed, and a fatal recurrence of the hemorrhage did not take place until after several weeks, the patient in the mean time taking considerable exercise under the advice of a practitioner who scouted the idea of aneurism. The progress of the aneurism varies much in different cases, the duration of life being in some cases but a few months, and in some cases several years. In a considerable number of cases life is destroyed before rupture takes place. Pressure on the trachea, œsophagus, vena cava, thoracic duct, or irritation of the recurrent laryngeal nerve may lead to a fatal result, or the patient may be cut off by some intercurrent affection. Organic lesions of the heart coexist in a certain proportion of cases. These of course involve distress and danger in proportion to their nature and extent, and may prove the immediate cause of death. Clinical observation shows that patients affected with thoracic aneurism rarely have pulmonary tuberculosis.

Recovery from thoracic aneurism sometimes takes place, but in general the only results to be hoped for from treatment are palliation of suffering and prolongation of life. With reference to these results all active exertions are to be avoided, and, as far as possible, emotional excitement. The body is to be well nourished if possible, but the diet should be unstimulating and alcoholic stimulants should be interdicted. Liquids should be taken sparingly. The action of the heart, if abnormally strong, is to be diminished by sedative remedies, and perhaps, if the patient be full-blooded, in some cases by small abstractions of blood. It is highly important not to impoverish the blood, and anæmia if it exist calls for the treatment appropriate to that condition. Pain and other incidental symptoms are to be palliated by appropriate remedies. If spasm of the glottis be induced through the recurrent laryngeal nerve to such a degree as to endanger life, laryngotomy is warrantable, if not advisable, with a view to palliation and the prolongation of life. This operation will of course be of no avail if the obstruction be due to pressure of the aneurismal tumor on the trachea.

The progress of the aneurism is retarded by the deposit of successive layers of fibrin within the aneurismal sac. It is in this mode that a cure sometimes takes place. It is desirable, therefore, that the blood should be rich in fibrin, and it is probable that the deposit is more likely to take place in proportion as the action of the heart is slow. Cardiac sedatives—namely, aconite, digitalis, and the veratrum viride—may in this way be useful. Certain remedies have a more direct curative effect in some cases of aneurism. At the present time the iodide of potassium is to be relied upon more than any other known remedy. Cases in which a cure was apparently effected by this remedy have been reported by Roberts, Balfour, Bouillaud, and others. I have witnessed remarkable improvement under the use of this remedy in several cases.¹ The doses should be increased up to a point of comfortable tolerance and continued for a considerable period. The iodide of potassium should be faithfully tried in all cases of thoracic aneurism.

¹ Vide *Clinical Medicine*, 1879.

[In the treatment of aneurism not curable by surgical means the most important indication is rest in bed. The difference between the number of the heart-beats in the recumbent and sitting positions is at least 20. In one of Tuffnell's patients it was 35, which is equal to more than 50,000 in the twenty-four hours. No remedy in the Pharmacopœia could, he says, produce so striking an effect. The same author recommends a restricted diet amounting to 10 ounces of solid and 8 of liquid food in twenty-four hours, namely: for breakfast, 2 ounces of bread and butter and 2 ounces of milk; for dinner, 3 ounces of mutton and 3 ounces of potatoes or bread; and for supper, 2 ounces of bread and butter and 2 ounces of tea. By this method undoubted cures have been effected.]

There is a semi-surgical method of treating thoracic aneurism which has been successful in a few cases. I refer to galvano-puncture. McCall Anderson reports several cases treated in this manner, and certainly with very encouraging results. The mode of proceeding is as follows: The needles are insulated to within half an inch of their extremities and oiled before being introduced into the aneurismal sac. They should also be disinfected. Althaus recommends that two needles be inserted into the sac and that both be connected with the battery. If this plan be followed, a small firm clot will form around the positive pole and a larger softer clot around the negative pole. Anderson advises that only one needle be inserted in the sac and that it be connected with the positive pole, a zinc plate connected with the negative pole being placed on the chest in the vicinity of the tumor. A large sponge saturated with salt water is interposed between the zinc plate and the integument. The form of electricity employed is the continuous galvanic current, the strength of which should not be great. Anderson employed in his cases from six to eight cells of Stöhrer's battery, and in several instances the latter number was too great. The length of the sitting should not exceed half an hour.

With the object of inducing coagulation of its contents, foreign bodies such as horse-hair, fine wire, and the perchloride of iron have been introduced into the sac. These proceedings have been attended with a certain measure of success, but are only applicable when the tumor is distinctly outlined and has therefore attained a considerable size.—H.]

SECTION THIRD.

DISEASES AFFECTING THE HÆMATOPOIETIC SYSTEM.

CHAPTER I.

DISEASES OF THE HÆMATOPOIETIC SYSTEM.

Introductory Remarks.—Simple or Benign Anæmia.—Chlorosis.

IN this section will be considered certain diseases which are believed to be the result of disturbances in the blood-forming functions. It is, therefore, proper to refer these diseases to the hæmatopoietic¹ (or blood-forming) system. As the constituents of the blood-plasma are derived more or less directly from the ingesta, we understand by the hæmatopoietic system especially those organs and parts in which resides the function of producing the formed constituents of the blood—namely, the red and the white corpuscles. The name cytogenic organs has also been employed in the same sense. Our knowledge as to the development of the blood-corpuscles and as to the situations in which they are formed is very imperfect, notwithstanding the abundant researches devoted to these subjects, especially during the last few years. The parts to which has been assigned, with more or less probability, the function of forming blood-corpuscles after birth are the lymphatic glands, the spleen, the red marrow of the bones, and the blood itself.² To these parts,

¹ From *αἷμα*, blood, and *ποιῶ*, to make.

² White blood-corpuscles are derived from the lymphatic tissues of the body, especially from those organs where this tissue is most abundant—viz. the spleen, the lymphatic glands, and the red marrow of the bones. Red marrow, which in embryos and young infants exists in all of the bones, is present in the adult in the bones of the trunk, but is replaced by fatty marrow in the long bones of the extremities. In severe forms of anæmia the yellow or fatty marrow is often changed into red or embryonic marrow.

It is now generally held that the red blood-corpuscles are in some way derived from the nucleated red blood-corpuscles which are constantly present in the red marrow of the bones, but the manner of their development is not understood. Some believe that red blood-corpuscles are formed out of ordinary white blood-corpuscles, the nucleated red corpuscles being a transitional stage in this formation (Neumann). Another view is that certain colorless cells, which are thought to differ from ordinary white blood-corpuscles in the possession of vesicular, reticulated nuclei and in the mode of cell-division, give origin first to nucleated red blood-corpuscles, and these to ordinary red corpuscles (Löwit). Still others consider that the nucleated red blood-corpuscles are independent cells which by indirect cell-division produce red corpuscles (Bizzozero). Karyokinetic figures are abundant in various cells found in the osseous medulla, including the nucleated red blood-corpuscles. Under normal conditions, when the new red blood-corpuscles enter the circulation they are fully formed and devoid of nuclei. There is no proof that red blood-corpuscles are formed after birth elsewhere than in the marrow of the bones. A full consideration of these as well as of other problems in the physiology of the blood-corpuscles will be found in the "Cartwright Lectures on Certain Problems in the Physiology of the Blood-corpuscles," by William Osler, *The Medical News*, April 3 *et seq.*, 1886.

therefore, may be given, at least provisionally, the name hæmatopoietic system.

The diseases treated of in this section are grouped together, not so much with reference to the anatomical parts affected as in consequence of certain common characteristics. In the majority of these affections we cannot explain, by known anatomical changes, the alteration which exists in the composition of the blood. This is true in spite of the fact that in many cases pathological changes have been recognized in parts thought to belong to the hæmatopoietic system. It is probable that a relation of cause and effect exists between these changes and the blood-alterations, but the connection is rendered obscure by our ignorance as to the life-history of the blood. The anatomical changes found in some of the diseases considered in this section are to be regarded as secondary rather than as primary elements in the disease. We must content ourselves frequently with establishing the existence of some disturbance in the blood-forming function, without attempting to refer the disturbance to anatomical changes.

A common and distinctive characteristic of the diseases of the hæmatopoietic system is the presence of anæmia, usually of a grave form. This anæmia is called *essential*, in that it is not referable to diseases which interfere secondarily with the composition of the blood, such as Bright's disease, cancer, and phthisis, but is attributable to a direct interference with the blood-forming or blood-destroying functions. In many of the essential anæmias no anatomical change has been found in the body which can, with any probability, be assigned as the cause of the anæmia; and in others, as in leucocythæmia and pseudo-leucocythæmia, there are morbid changes which may be considered as interfering more or less directly with the formation of the blood-corpuscles. In these diseases the normal ratio between the consumption and the renewal of the corpuscular elements of the blood is disturbed. The destruction of the corpuscles may be abnormally increased (hæmophthisis), or the reproduction of corpuscles may be diminished below the normal amount (anæmatosis), or both conditions may be combined. It is usually impossible to determine in a given case which of these causes is at work. The result of this disproportion between consumption and renewal is impoverishment of the blood, or anæmia, which, together with the consequent disturbance of nutrition, forms the dominating factor in all of these diseases. It will be found, therefore, that these affections have much in common in their clinical history. They are for the most part insidious in their onset and chronic in their course. As a rule, their causes are obscure, and, with the exception of simple anæmia and chlorosis, their prognosis is grave.

Simple or Benign Anæmia.

The terms simple and benign may be used to designate anæmia when not pernicious or an element of the other affections embraced in this section, and when diseases of which the anæmic condition is symptomatic, such as phthisis, empyema, carcinoma, etc., may also be excluded. It may be said that, as thus restricted, anæmia is only a symptom. It occurs, however, under various circumstances, and for convenience it may be considered in the light of an individual disease with as much propriety as certain other events which are symptoms—for example, jaundice. Simple or benign anæmia, as just defined, enters largely into medical practice.

The obvious causes are—*first*, loss of blood, or hemorrhages; *second*, defective assimilation; and *third*, expenditure of certain blood-constituents, as in lactation and pregnancy. Hemorrhages occur under a great variety of circumstances. In women menorrhagia and flooding with labor are frequent

causes. Defective assimilation may depend on a lack of food in sufficient quantity or of food sufficiently nutritious; and with abundant alimentation the processes of digestion may be so impaired as to prevent proper assimilation. Lactation and pregnancy are frequent causes. To these causes may be added certain toxic agencies which interfere with hæmatopoiesis—namely, lead, malaria, etc. Simple or benign anæmia is a sequel of diseases which have kept in abeyance either alimentation or assimilation. Women become anæmic much oftener than men, irrespective of the causes which are peculiar to the sex—namely, pregnancy, lactation, and menorrhagia.

Anæmia gives rise to a multiplicity of morbid phenomena representing especially disorder of the nervous system. The more frequent and prominent are as follows: mental depression, anxiety respecting health, irritability of mind, want of buoyancy and energy, a feeling of lassitude, and a painful sense of inertia or indolence. The feeling of incapacity for muscular exertion is often greater than the actual loss of muscular power. The physical and mental powers are especially depressed during digestion. Palpitation of the heart is frequent, and organic disease is greatly feared by the patient. Neuralgia in various situations is likely to occur, and in women hyperæsthesia of the abdominal walls, simulating peritonitis. The varied symptoms formerly and recently described as due to spinal irritation are liable to occur in connection with anæmia. The varied phenomena considered as hysterical are often associated with, and more or less dependent upon, anæmia. The special relations between the red corpuscles and the nervous system are shown by the neuropathic phenomena to which anæmia gives rise. These phenomena may be said to constitute the pathological expressions of this morbid condition of the blood. The different organs of the body in cases of anæmia are deficient in functional power in proportion to the quantity of blood which they receive in health. The surface of the body is cool and the extremities are frequently cold. The ability to endure cold is lessened. There is diminished endurance of muscular as well as mental exertion. Generally, the face, especially the prolabia, and the mucous membrane in situations where it can be seen, are pallid. The facies often at once denotes anæmia. In some persons, however, the anæmic condition, as determined by physical signs and its pathological phenomena, exists not only without pallor, but with even a rosy complexion. Pallor of the prolabia may be noticeable in the morning or if the patient be fatigued, and it may disappear under excitement. The action of the heart is feeble and easily disturbed, becoming rapid from slight causes. The respirations are panting on exercise. Digestion is labored. The urine often has a low specific gravity from a deficiency of urea, and is notably limpid from a diminution of pigment. The cerulean eye—that is, a dark-blue tint of the globe, owing to a semi-transparency of the conjunctiva—may be a more marked feature than pallor of the face or the prolabia.

The symptomatic evidence generally renders the recognition of anæmia easy. Certain auscultatory signs confirm the diagnosis. The continuous murmur in the neck, known as the *venous hum*, is rarely wanting, and is not often present if there be not anæmia. A frequent sign is a systolic bellows murmur, referable to the carotid arteries. Not less frequently systolic murmurs are heard at the base of the heart, produced within the aorta and the pulmonary artery. The significance of these murmurs depends on their hæmic origin, and this is rendered evident by the absence of signs denoting lesions of the heart or arteries. These hæmic murmurs are useful not only in the diagnosis of anæmia, but as criteria by which the physician is aided in deciding whether the anæmic condition continue or whether it have been removed by measures of treatment. The diagnosis may be rendered demon-

strative by ascertaining the number of red corpuscles and the amount of hæmoglobin.

In order to decide that the anæmia is simple or benign, the pernicious form, leucocythæmia, and pseudo-leucocythæmia—diseases considered in this section—are to be excluded, and also all other important diseases which involve, as a symptom or an effect, the anæmic condition. To exclude these diseases is generally not difficult. Although, as has been seen, anæmia stands in a causative relation to a large number and a great variety of pathological phenomena, there are not present symptoms which denote a grave condition. Pyrexia is wanting, and the general nutrition of the body may be well maintained. With reference to the exclusion of important diseases, it is necessary that the physician be qualified to appreciate the phenomena referable to the anæmia. In most instances the causes of the anæmia are apparent, and their existence is to be taken into account in the diagnosis. Moreover, the diagnosis is often corroborated by the speedy effect of appropriate treatment.

The PROGNOSIS in cases of simple or benign anæmia is generally good. Provided the causes do not continue in operation, recovery may be expected. Different cases differ much as regards the rapidity of progress toward recovery. In the exceptional cases which are treated unsuccessfully there is reason to conclude that the want of success may be due to an innate defect in the hæmatopoietic system.

Anæmia may be associated with other diseases, the latter occurring in persons already anæmic. It is of great importance in practice to take cognizance of this association. The phenomena of the associated diseases are modified by the antecedent and coexisting anæmia. Tolerant of diseases and recuperation are thereby impaired. Whatever may be the disease thus coexisting with anæmia, but without involving necessarily any relation of cause or effect, the anæmic condition claims recognition, and is to be considered in connection with the indications for treatment. With the different functional affections of the nervous system anæmia is associated as a rule, standing often to them, measurably, in a causative relation.

In the TREATMENT of anæmia causal indications are of primary importance. The causes in individual cases are to be ascertained, and if possible removed. Hemorrhages are to be arrested or restrained. Alimentary supplies should be sufficiently abundant and varied. It may be requisite that lactation be discontinued. It is sometimes advisable to caution against pregnancy. Digestion and assimilation are to be promoted by appropriate medical and hygienic treatment. The patient is to be withdrawn from the operation of toxical causes, lead, malaria, etc., and as far as practicable from all unsanitary influences which indirectly lead to the anæmic condition.

The quantity of wholesome food should be equal to, but not exceed, the digestive powers. Appetite and digestion should be promoted by quinia, salicin, and other tonic remedies. The articles of diet should be made attractive. Dyspeptic ailments are to be treated according to the indications to be hereafter considered. (Vide Section IV., Chapter IV.) Out-of-door life, recreation, change of scene, daily sponging of the body, sea-bathing, and all hygienic measures which have a favorable influence on assimilation and conduce to invigoration are useful.

The preparations of iron have a specially curative agency. Their *modus operandi*, with our present knowledge, cannot be satisfactorily explained. Doubtless the fact that iron is a constituent of the red corpuscles of the blood affords a partial explanation. Nothing in practical medicine is better established than the value of iron as a remedy in simple or benign anæmia. Its value is often attested by its efficacy even when the causes of the anæmia cannot be removed and when other circumstances are unfavorable. If in any

case it have no curative effect, there is reason to suspect that the anæmia is not simple or benign. On the other hand, the efficacy of the remedy is evidence that the anæmia is of that character.

Of the different preparations of iron it is difficult to give decided preference to any one over the others. A physician is likely to have his favorite preparation, but that the choice is not based on the comparative merits of a considerable number is shown by the fact that almost every preparation has its advocates. Iron reduced by hydrogen, the citrate, the hypophosphite, the tincture of the chloride, the tartrate, the carbonate, and the compound mixture are all eligible preparations. It is a good plan to change from one preparation to another after a few weeks, giving thus several, or it may be many, of the different preparations in succession.

The chalybeate remedies should be given in moderate doses after meals—that is, during the process of digestion—and in order to secure their full efficacy they should be continued uninterruptedly for a considerable and perhaps for a long period. It is well to state beforehand to a patient that all the good which they may accomplish is not to be expected within a brief period. This statement will be likely to secure patience and perseverance. Patients often think that they do not tolerate iron in any form. In general, they are self-deceived in this regard, as may be demonstrated by their ability to take it with no inconvenience if it be given without their knowledge.

Arsenic is another remedy often of much efficacy in the treatment of anæmia. It should be given in small doses, which should not be increased, and it should be continued for a considerable period. The effect of this remedy is sometimes more marked than that of chalybeates.

Wine, especially Burgundy, is often useful. Here, as in other affections, alcoholics are of use only when they have a cordial effect, promoting assimilation and perhaps diminishing waste of tissues, without any excitant effects. Alcoholic excitation is always to be avoided, and the immediate effects, if in any way uncomfortable or disturbing, are contraindicating. Malt liquors sometimes agree better than wine. Spirits, as a rule, are not appropriate. As to the kind of wine or malt liquor to be preferred, experience in each case is to be the guide. Cod-liver oil, if it do not impair the appetite or disorder digestion, contributes to the reproduction of red corpuscles. If not well borne the extracts of malt may be substituted.

In cases of anæmia assurances of the absence of any grave disease and an encouraging prognosis are often of much weight as a therapeutical factor. Despondency is an effect of the anæmic condition upon the mind, and the physician in many cases has it in his power not only to remove gratuitous apprehensions, but to do not a little toward a cure by holding out proper expectations of recovery.

Chlorosis.

Although the chief element in chlorosis is undoubtedly anæmia, it presents certain peculiarities which render its separate consideration appropriate. The impoverishment of the blood in chlorosis has reference chiefly to the red corpuscles, and in a less degree to the albuminous constituents of the plasma. There is a reduction in the quantity of hæmoglobin in the red corpuscles, either with or without a diminution in their number. It is especially in chlorosis that a reduction in the percentage of hæmoglobin has been found without a corresponding decrease in the number of red corpuscles. Cases have been observed in which the number of red corpuscles was normal, while less than one-half of the proper amount of hæmoglobin was present. This condition of disproportionate diminution of hæmoglobin is called achroio-

cythæmia or oligochromæmia. Usually, however, the number of corpuscles is lessened, as well as the percentage of hæmoglobin.

According to Virchow, an almost constant lesion in chlorosis is arrest of development of the vascular system, as indicated by the small size and the thin coats of the aorta and other arteries. The intima of the arteries sometimes contains yellowish spots and streaks in consequence of fatty degeneration. Most observers do not consider these irregularities in the vascular system as a constant and essential change in chlorosis. Arrest in development of the female generative organs has been observed in cases of chlorosis, but, on the other hand, they often present no abnormalities. No especial importance, therefore, can be assigned to anatomical changes in these parts as entering into the causation.

[Sir Andrew Clark regards constipation as of such paramount importance in the causation of chlorosis that he proposes the term "fecal anæmia" as a synonym for the disease. This opinion is based upon certain signs and symptoms that are more or less common to all cases of chlorosis. Chief among these are digestive disturbances. The tongue is generally heavily coated at the base, large, flabby, and with its sides indented by the teeth. The breath is disagreeable, and sometimes, according to Clark, has a distinctly fecal odor. There is a sense of epigastric oppression after the ingestion of food. The bowels are either confined or inadequately relieved, and the feces generally consist of scybalous masses imbedded in an offensive mucus swarming with bacteria. Pain in the side, generally most marked on the left, is a common symptom, and is believed by Clark to have its seat in either the hepatic or splenic flexure of the colon. This view of the nature of the pain in the side is corroborated by the fact that it is sometimes relieved by large enemata of warm water. According to the authority just quoted, it is a common thing for young girls to neglect the calls of nature so far as the bowels are concerned. The feces accumulate, and by their decomposition ptomaines and leucomaines are generated and absorbed, and by their poisonous action produce the multiform symptoms of chlorosis. A treatment based upon the theory that chlorosis is due to fecal retention has been found eminently successful, and will be referred to later in detail.—H.]

Aside from the foregoing differential points, the term chlorosis is applied to anæmia occurring in girls at or near the period of puberty, usually between the ages of fourteen and twenty-four, the causes often not being apparent. The term denotes a greenish coloration pertaining to the facies, but this is by no means a criterion. By some writers chlorosis is regarded as a neuro-pathic affection not always associated with anæmia. While anæmia is a constant element, there are doubtless causes which act upon the nervous system primarily and more directly than by inducing impoverishment of the blood. The development of the affection is evidently in some way connected with the evolution of the sexual system. How far the causation may involve, on the one hand, ungratified sexual desire, or, on the other hand, unnatural self-abuse, it is difficult to say. There is ground for the belief that each of these causative agencies is not infrequently operative. Disappointment in love, the loss of relations, and crosses of various kinds may be involved. These less apparent and other secret causes may act in conjunction with those already stated as giving rise to simple or benign anæmia. (Vide p. 292.) Blondes are said to be more liable to become chlorotic than brunettes. The affection, however, is not exclusively confined to girls. It is occasionally, owing probably to similar causative agencies, met with in boys.

The symptoms which have been enumerated as belonging to the clinical history of simple or benign anæmia are more or less marked in cases of chlorosis. Fantastic perversions of appetite are not uncommon in chlorotic girls,

manifested by a craving for chalk, slate, charcoal, and other innutritive substances. These perversions are somewhat distinctive of chlorosis. The other points in the differentiation from simple or benign anæmia are those which have been stated as characteristic of the chlorotic affection—namely, the sex, the age, the absence of an obvious adequate causation, the probable connection with the sexual instinct, and in some instances the reduction in quantity of the hæmoglobin of the blood without diminution in the number of red corpuscles. As in simple or benign anæmia, the diagnosis requires an exclusion of the graver diseases of the hæmatopoietic system and of other diseases of which anæmia is a symptom.

The TREATMENT of chlorosis embraces measures, the same as in simple or benign anæmia, relating to diet, out-of-door life, etc., adapted to the circumstances proper to individual cases; and the preparations of iron, as a rule, are not less indicated and not less efficacious. The rules for their administration are the same. Arsenic is sometimes highly useful. Mental hygiene is of special importance in proportion as causative agencies relate to the mind. Agreeable diversion and the moral effect of change of scene are often important measures of treatment. Occupations and sentiments which will displace sexual thoughts and desires in some instances have a radical efficacy. This statement will include the instances in which self-abuse can be ascertained.

[Sir Andrew Clark strongly recommends the following method of treating chlorosis: With careful attention to the diet and a tepid sponge-bath followed by brisk towelling night and morning, he prescribes the following mixture, to be taken twice a day:

R. Ferri sulphat.,	gr. xxiv ;
Magnes. sulphat.,	ʒvj ;
Acid. sulph. aromat.,	ʒj ;
Tinct. zingib.,	ʒij ;
Infus. gentian. comp. vel quassia,	ʒviij.—M.

S. One-sixth part twice daily, at eleven and twelve.

"Occasionally this acid mixture produces sickness, dries the skin, and is otherwise ill borne." In such cases he prescribes the following alkaline mixture:

R. Ferri sulphat.,	gr. xxiv ;
Sodii bicarb.,	ʒij ;
Sodii sulphat.,	ʒvj ;
Tinct. zingib.,	ʒij ;
Spt. chloroformi,	ʒj ;
Infus. quassia,	ʒviij.—M.

S. One-sixth part twice daily, at eleven and six.

Sometimes neither mixture agrees with the patient, and then he prescribes sulphate of iron in pill with meals and a saline aperient on first waking in the morning. By this plan Clark declares that nine out of ten cases of chlorosis recover in from one to three months, and by careful attention to the bowels, taking twice a week a pill composed of aloes, myrrh, and iron, the recovery will probably be permanent.—H.]

CHAPTER II.

LEUCOCYTHÆMIA.

THERE is a group of diseases characterized by a new growth of lymphatic tissue in various parts of the body. Lymphatic or adenoid tissue consists of reticulated connective tissue containing in its meshes lymphoid cells. This new lymphatic growth may be homologous or heterologous. It is homologous when in the form of hyperplasia of pre-existent lymphatic tissue, as of the spleen, lymphatic glands, and marrow of bone. It is heterologous when lymphatic tissue is produced in situations where it does not normally exist, as in the liver, kidney, skin, etc. It has been proposed to call these diseases connected with hyperplasia of the lymphatic structures, lymphatic diseases. Common to all of these diseases is profound anæmia, generally progressive and fatal. The basis of classification usually adopted depends upon the number of white corpuscles present in the blood. When the pathological changes in the lymphatic tissues above mentioned are associated with marked increase in the number of white corpuscles, the name leucocythæmia is given to the disease. When the same pathological changes exist with anæmia, but without excess of white corpuscles, the disease is called pseudo-leucocythæmia. Pseudo-leucocythæmia includes splenic anæmia, lymphatic anæmia, and probably some cases of so-called progressive pernicious anæmia.

Leucocythæmia.

Leucocythæmia or leukæmia is a chronic disease characterized by a persistent and considerable increase in the number of white corpuscles in the blood. A temporary excess of white corpuscles, usually moderate in amount, is called leucocytosis. Alterations in the marrow of the bones, enlargement of the spleen, and hyperplasia of the lymphatic glands constitute, either singly or combined, the leading anatomical changes in leucocythæmia. Leucocythæmia is usually divided into three forms, called splenic, lymphatic, or medullary according as the changes in the spleen, lymphatic glands, or the marrow of the bones seem to be primary and predominant. The medullary form is also called myelogenic leucocythæmia. These forms are usually combined with each other to a greater or less extent, and hence the terms lymphatico-splenic, medullo-splenic, etc. These subdivisions of leucocythæmia are not associated with essential differences in the clinical history, and are of importance chiefly as indicating that the anatomical changes may predominate in certain organs. There has been much difference of opinion as to the part primarily affected in leucocythæmia. The prevailing view has been that the primary alteration is in the spleen, or more rarely in the lymphatic glands. Changes in the marrow of the bones have been found, as a rule, since attention was called to them by Neumann. This pathologist believes that they are constant and form the primary lesion. It seems, however, probable that the changes in the spleen, the lymphatic glands, and the marrow of the bones are co-ordinate, and in proportion to their degree of equal importance; but the changes may be extensive in one part and insignificant in the other parts.

The pathognomonic change in the *blood* may be detected during life in a drop drawn from the finger, or after death by examining the blood in the heart and vessels. The blood is paler than normal, and of a brownish-red, sometimes almost of a chocolate, color. The clots found in the heart and

vessels are of a yellowish color in their superficial layers, and of a soft, viscid consistence, so that they bear some resemblance to very thick pus. The proportion of white corpuscles to red in health, although varying within wide limits, is on the average about 1 white to 500 red. In leucocythæmia there is often 1 white to 10 or 8 of the red, and there may be even 1 white to 3 or 2 red. In one case related by Sørensen there were 3 white to 2 red. In the great majority of cases the proportion during the course of the disease exceeds 1 white to 20 red corpuscles. Although in general the white corpuscles in leucocythæmia resemble the ordinary white blood-corpuscles, there are certain differences to be noted. In addition to the ordinary polynuclear white blood-corpuscles, leukæmic blood often contains a large number of mononuclear corpuscles, of which some are small with a narrow rim of protoplasm, like lymph-cells, while others are large with a broad mantle of protoplasm, like cells in the spleen and in the marrow of the bones. According to Virchow, an abundance of small corpuscles is indicative of lymphatic leukæmia, and an abundance of large corpuscles, of splenic leukæmia; but there are doubts as to the correctness of this view. Most of the leucocytes in leukæmia are more sluggish in their amœboid movements than ordinary white blood-corpuscles.¹ Nucleated red blood-corpuscles may be present in leukæmic blood, although not often in large number. The blood-plates are sometimes increased in number, but they may be fewer than normal. The number of white blood-corpuscles may vary considerably within a short time. Eisenlohr describes a case in which the excess of white corpuscles nearly disappeared during a febrile attack, to return again after its subsidence.

The number of red blood-corpuscles is usually considerably diminished, although exceptionally it may be normal. The red corpuscles may be reduced to one or two millions, or even less, per cubic millimetre.

The fresh blood is always alkaline, but it has a tendency to rapidly assume an acid reaction. The specific gravity of the blood is lessened. The amount of fibrin is said to be increased.

Some degree of splenic enlargement is usually present in all forms of leucocythæmia. In *splenic* leucocythæmia, which is the most frequent variety, the enlargement is often extreme. According to Gowers,² the average weight of the spleen in splenic leucocythæmia is a little less than 6 pounds, and its average length, 11½ inches. Leucocythæmic spleens weighing 16 and 18 pounds have been recorded. The increase in size is usually uniform in all directions. The notches upon the anterior border, the recognition of which may aid in the diagnosis, are often exaggerated. The capsule of the spleen frequently presents thickened white patches. There may be adhesions between the surface of the spleen and surrounding parts. The consistence of the organ is usually increased, but it may be soft, especially in the early stages. The cut surface of the spleen may be uniformly brownish-red in color, or the Malpighian bodies may be prominent as whitish dots, or, when greatly enlarged, they may even appear as tumors in the substance of the spleen. The whitish trabeculae may be much thickened, especially in the late stages. The spleen

¹ Other peculiarities of the white corpuscles in leukæmia have been noted, especially by Ehrlich. Some of the corpuscles may contain molecules of fat, others, granules of brown pigment. There is an increased number of corpuscles containing granules which stain with eosin (eosinophilic cells). There may be corpuscles containing granules which stain with basic aniline dyes (Mastzellen). These do not occur normally in the blood. The mononuclear cells may contain granules which stain with neutral aniline res. like granules normally found in polynuclear cells (neutrophilic granules). It has been suggested that many of the corpuscles are not white blood-corpuscles, but are colorless corpuscles, such as are intended normally for the formation of nucleated red blood-corpuscles in the medulla of bone.

Changes are also observed in leucocythæmia in *non-lymphatic organs*. These changes are either diffuse or circumscribed and nodular. The diffuse alteration consists in the distension of capillaries and the infiltration of the tissues with white blood-corpuscles. The circumscribed changes, which are not common, consist in the nodular accumulation of leucocytes either with or without a new growth of adenoid reticulum between the cells. To these nodular accumulations the names heteroplastic leucocythæmic growths, lymphomata, and lymph-adenomata are applied.

The liver is enlarged in the majority of cases, especially those of the splenic variety. A weight of six or seven pounds is not uncommon. Virchow describes leukæmic livers weighing from eight to fourteen pounds. The enlargement is due to a distension of the capillaries with leucocytes, and to the infiltration of the tissue between and within the lobules with these cells, probably in consequence of their escape from the vessels. Disseminated whitish nodules, usually minute, but sometimes of considerable size, consisting of lymphoid cells, are frequently found in the interlobular tissue. These nodules are called lymph-adenomata when an adenoid reticulum can be demonstrated between the cells.

The kidneys are not infrequently enlarged. The changes are diffuse and circumscribed as in the liver. Parenchymatous alterations may or may not be present. Tizzoni has described infiltration and nodules of lymphoid cells in the testicles. Leucocythæmic growths may furthermore be scattered through different parts of the body, as the alimentary tract, the lungs, the serous membranes, the brain and the retina, the skin, etc. Nuclear figures indicating cell-proliferation have been found in the lymphoid cells in these growths.

Next to these accumulations of lymphoid cells, the frequent occurrence of hemorrhages in leucocythæmia deserves mention. Subserous ecchymoses, hemorrhages into serous cavities and from mucous membranes, and retinal and cerebral hemorrhages may be mentioned as frequent and important. The gums and the mucous membrane of the mouth and pharynx may be swollen and ulcerated. The lymphoid growths in the intestine may ulcerate. Pronounced fatty degeneration, especially of the heart and kidneys, has been repeatedly observed.

Various abnormal substances have been found in leucocythæmic blood. These are bodies analogous to glutin, hypoxanthin, leucin, tyrosin, and acetic and formic acids. These substances have not been uniformly discovered. Some are normally present in the spleen. There are frequently found after death minute colorless, elongated, octahedral crystals called Charcot's crystals. They have been detected in the blood, the spleen, the marrow of the bones, the liver, and even in other parts. They are thought to be of an albuminous composition. Although most abundant in leucocythæmia, they have been found in other conditions, and they may form after death in healthy marrow.

There have been several theories as to the relation in leucocythæmia between the morbid change in the blood and the hyperplasia of the lymphatic structures. Bennett, to whom we owe the first recognition, in 1845, of leucocythæmia as a distinct disease, maintained that the change in the blood was primary; and the same view has had its advocates in recent years. Most modern pathologists, however, have accepted Virchow's doctrine that the increase of white corpuscles in the blood is secondary to the pathological changes in the lymphatic organs to which is assigned a blood-forming function with lymph-adenoid marrow, but without changes in the spleen and lymphatic glands. Neumann also has observed cases in which the medulla of the bones was involved without a affection of the spleen or lymphatic glands.

tion. Some have emphasized chiefly the affection of the spleen, and others, that of the marrow of the bones. According to one theory, there is an insufficient transformation of white into red corpuscles in the blood-forming organs and in the blood; according to another, there is increased production of white corpuscles, an exaggeration of the cytogenic function. The most probable view seems to be that there is increased formation of white corpuscles in the spleen, the lymphatic glands, and in the marrow of the bones, sometimes chiefly in one, and sometimes in all of these organs. From these hyperplastic organs the corpuscles are swept in large numbers into the blood and the lymphatic currents. Either the production of red corpuscles is diminished or their destruction is increased.¹

The development of leucocythæmia, as determined by SYMPTOMS, is usually slow and imperceptible. Before the character of the disease is determinable general debility, indisposition to exertion, disorders of digestion, and other indefinite ailments have existed for one or two years, and sometimes for a much longer period. In exceptional cases, oftener in children than in adults, it is developed within a few weeks. Early and prominent symptoms are those referable to impoverishment of the blood. Pallor of the face, prolabia, and mucous membranes, and dark coloration of the eyeballs, are more or less marked, as in cases of benign anæmia and chlorosis, for which the disease in its early stages is liable to be mistaken.

Coincident with the anæmic symptoms is enlargement of the spleen. This enlargement, if not great, may not have attracted the attention of the patient. The enlargement, however, is often so great as to form a splenic tumor which occasions a projection obvious to the eye. The tumor may occupy a considerable part of the abdominal space. It has been mistaken for an ovarian tumor. It may cause dislocation of the heart, and, by pressure on the diaphragm, interference with respiration. Pain and tenderness referable to the enlarged spleen are frequent but not constant symptoms.

In the so-called lymphatico-splenic variety there is swelling of the glands of the neck, groin, and axilla, forming soft, movable tumors rarely of much size. The mesenteric glands are sometimes enlarged, so as to be felt through the abdominal walls. The bronchial glands may be enlarged, but rarely to an extent sufficient to occasion notable bronchial obstruction. The glandular swelling may occur either early or late in the progress of the disease. If the disease involve the marrow of bones (medullo-splenic and myelogenic leucocythæmia), there may be found over these, particularly the sternum, tenderness and sometimes swelling, but, as a rule, local symptoms are wanting.

Dyspnœa is a symptom more or less prominent, attributable to the paucity of red corpuscles. It may be caused, in addition, by enlargement of the spleen and also of the liver, the latter occurring frequently. The dyspnœa is increased, and may be rendered extreme by hydrothorax in connection with general dropsy and in some instances pleurisy with effusion.

General dropsy occurs sooner or later in a large proportion of cases. It may be independent of cardiac or renal disease, but the latter is a complication in some cases. Hydro-peritoneum is sometimes produced by the pressure of enlarged glands on the vena portæ, and the accumulation of liquid may be so large as to call for paracentesis.

The action of the heart is increased in frequency, often considerably, and is attended by paroxysms of palpitation, during which the pulse is 150 or more per minute.

¹ The idea has been advanced that leucocythæmia and pseudo-leucocythæmia are infectious diseases dependent upon some special organism in the blood. Some pathologists class the lymphomatous growths of these diseases among the infectious tumors. This idea, which is not without some probability, is at present purely an hypothesis.

are not uncommon. Hæmic murmurs are common, as in benign anæmia and chlorosis. The temperature of the body is in most cases raised. Different cases differ in respect of the amount of pyrexia. It is generally moderate (from 100° to 102° Fahr.). Occasionally there is hyperpyrexia. Usually, there are febrile exacerbations in the evening. The temperature is found to fluctuate between wide limits at different times in the same case during the progress of the disease. The course of the disease is rapid in proportion to the degree of persistent pyrexia.

The liability to hemorrhage is such that a hemorrhagic diathesis may be said to constitute a prominent feature of the disease. Mosler emphasizes the importance of recognizing this diathesis as contraindicating surgical operations in cases of leucocythæmia. He relates a case in which the patient nearly died from an insignificant operation, the bleeding having been stopped only by continuous digital compression.¹ Hemorrhages may occur early in the disease. The most frequent seat is the nose. Epistaxis may prove the immediate cause of death. Enterorrhagia, gastrorrhagia, and menorrhagia are not rare. Bronchorrhagia and hæmaturia have been observed. Cerebral hemorrhage is a cause of death in some cases. Cutaneous ecchymoses are among the events incident to the disease, and extravasation beneath the skin, in muscles, inclusive of the heart, and into joints. Eisenlohr has reported a case in which peripheral paralysis of several cranial nerves was caused by hemorrhage into their sheaths.² Friedländer³ has reported a case in which the symptoms of cerebral tumor were caused by leucocythæmic growths in the brain.

Among events pertaining to the digestive system may be mentioned inflammation of the pharynx and mouth, accompanied sometimes with ulcerations and sometimes with bleeding from surfaces not ulcerated. Tumors of the character of lymphoma are sometimes developed in the throat. The appetite varies in different cases, and at different periods in the same case. It may not at first be diminished, and it may even be inordinate; but in the latter part of the disease there is generally anorexia. Vomiting is an infrequent symptom. Diarrhœa is a frequent symptom, and the dejections are sometimes dysenteric. Jaundice is an occasional event.

The urine has an excess of uric acid. Hypoxanthin, formic acid, and lactic acid have been found in small quantities—not, however, constantly. Albumen in any considerable quantity and casts denote the existence of renal disease as a complication.

Salzer was the first to call attention to persistent priapism without seminal emissions or sexual desire as an occasional symptom in leucocythæmia.⁴ Others have observed this symptom. Dr. G. L. Peabody has reported a case.⁵ Another case has been reported by Dr. G. F. Wetherell.⁶

The following morbid appearances in the retina have been observed by means of the ophthalmoscope: A pale appearance of the retinal vessels, hemorrhagic spots with white centres from an accumulation of lymphoid cells, whitish streaks, and cloudiness of vessels about the optic papilla. The name leucocythæmic retinitis has been applied to these changes. They may or may not give rise to notable disturbance of vision. The retinal hemorrhage may be sufficient to cause blindness. Headache, vertigo, feebleness of the mental faculties, delirium, and chronic derangement of mind occasionally enter into the clinical history. To these may be added impairment of hear-

¹ "Ueber hämorrhagische Diathese bei Lenkämie," *Zeitschrift für klin. Medicin*, Bd. 1, p. 265. He observed a case in which priapism lasted seven weeks, and when this symptom disappeared the power of erection was lost.

ing, furuncles, and pustular eruptions on the skin. In a case of leukaemia with deafness Politzer found leukaemic growths in the internal ear.

The limits of the *duration* of leucocythæmia are far apart. In very rare instances it runs a rapid course, ending within a few weeks. On the other hand, its duration may extend over many years. The average duration is about two years. It is not always easy to ascertain the duration, owing to difficulty of fixing the precise date of the origin of the disease. The termination often depends on events which are incidental to the disease, or on complications, such as hemorrhage, apoplexy from extravasation, pleurisy, renal disease, diarrhœa, etc. If not dependent on any of these events, death is produced by slow asthenia.

The *PROGNOSIS* is as grave as possible after the disease has made a certain degree of progress. In some instances, early in the course it has ceased to be progressive and recovery has taken place. If, with great blood-changes, the spleen becomes much enlarged, and more or less of the grave events belonging to the clinical history have taken place, there is little or no ground, with our present knowledge, for any expectation of recovery. The most to be hoped for is that the disease will progress slowly, and that events which involve immediate danger may not occur. There are occasionally marked remissions in the progress of the disease.

The clinical history of leucocythæmia from the beginning to the end of the career of the disease contains diagnostic characters, but these are not sufficiently distinctive in all cases for the differentiation from pseudo-leucocythæmia and pernicious anæmia. In an early period of the disease, when a *DIAGNOSIS* is desirable, it is liable to be mistaken for other diseases in which anæmia coexists with splenic enlargement. A positive diagnosis, however, is always practicable by means of examinations of the blood. Delay or failure in the recognition of the disease is owing to neglect of the means by which the diagnosis is to be made.

The diagnostic criterion is a persistent and progressive increase of the white corpuscles of the blood beyond the limit of the variations embraced under the name leucocytosis. This name embraces a greater or less increase of the white corpuscles, occurring as a symptom in various diseases, the increase falling short of that which constitutes the criterion of leucocythæmia. The rule generally accepted as regards the increase requisite for the diagnosis is a proportion of 1 white corpuscle to 20 red corpuscles. As already stated, the proportion is often much greater than this, the number of white being sometimes equal to that of the red corpuscles. On the other hand, in the early part of the disease the proportion may be considerably less than 1 in 20; and if on repeated examinations the proportion be found to progressively increase, there can hardly be doubt as regards the diagnosis.

The method of examination ordinarily employed is to obtain a drop of blood by pricking the finger of the patient, and, placing it in the field of the microscope, to estimate with the eye the relative proportion of the white and red corpuscles. A more accurate method is to add to a measured quantity of blood a definite quantity of a 5 or 6 per cent. solution of sulphate of soda, in order to dilute the blood and to prevent the red corpuscles from forming rouleaux. The field of the microscope is divided into squares, by the aid of which the corpuscles can be easily counted. The squares are ruled either upon the eye-piece or upon the cell containing the diluted blood.¹ It is to be observed that the relative proportion of the white and red corpuscles does not

¹ A convenient apparatus for counting the corpuscles is the hæmacytometer of Gowers. Still more exact is the apparatus of Zeiss.

show the degree of actual increase of the former, inasmuch as the red corpuscles are almost always considerably, and sometimes very greatly, reduced in number. Hence, the most exact method is to ascertain the number both of white and red corpuscles in a given quantity of blood by means of the hæmacytometer.

[No well-marked case of leucocythæmia can escape detection if the blood be properly examined. It is evident at a glance that the white cells as a whole are abnormally increased in number, but it is quite another thing to determine the relative share of the different varieties of white cells in this increase. It is well known that there are in normal blood various kinds of white cells, which may be classified either morphologically or in accordance with their reactions to various staining substances. Morphologically we recognize small and large lymphocytes, both of which are mononuclear, polynuclear leucocytes, and mononuclear transition forms. According to the second method of classification, the white cells are divided with reference to the affinity displayed by their protoplasmic granulations for certain coloring matters. The latter is the classification generally adopted by hæmatologists, whose leader in this line of research is, confessedly, Ehrlich. Owing to the researches of this observer, an entirely new nomenclature has arisen, and we now speak of cells that are eosinophile, basophile, neutrophile, and amphophile. In normal blood the great majority of the white cells are neutrophile, whereas in leucocythæmia the basophile and eosinophile cells are often very abundant. It was at one time supposed by Ehrlich that an increase in the number of the eosinophile cells was a characteristic sign of leukæmia, and that by it the diagnosis between leucocytosis and leucocythæmia could be readily made in doubtful cases. This theory has not been confirmed, and Ehrlich himself has abandoned it. In individuals free from leukæmia an increase in the eosinophile cells has been observed, and, on the other hand, in well-marked cases of leukæmia the eosinophile cells may be absolutely but not relatively increased; in other words, the leukæmic state of the blood may be chiefly due to the increase of other elements.

Leukæmic blood is characterized not only by excess of elements normally existing in the blood, but by the appearance of a cell not seen under any other circumstances. This is the so-called myelocyte. It is as large as, or even larger than, the large lymphocytes of normal blood, and differs from the latter in that it contains a large number of neutrophilic protoplasmic granulations. It is in all probability derived from the bone-marrow.—H.]

Leucocythæmia occurs at all periods of life, it having been observed in infants soon after birth and in extreme old age. In the great majority of cases, however, patients are between twenty and fifty years of age. It is less rare in men than in women. Social position has no marked influence on its causation. It occurs in women sufficiently often after parturition to show some causative connection. In a considerable proportion of cases patients with this disease have either had malarial fever or have been exposed to malaria. The disease is less rare in malarial districts than in those in which the periodical fevers do not occur. It is therefore reasonable to attribute to malaria a certain degree of causative agency. The white corpuscles have been found in some cases to contain black pigment-granules, such as are characteristic of malarial disease. Mosler applies to these cases the name *melano-leukæmia*.

The disease in a few instances has been preceded by local injury in the splenic region. There is little or no ground for attributing the disease to syphilis. In most cases the disease is developed in persons who at the time

of its development were apparently in good health. These statements express all that is at present known of the etiology.

Diminution of the volume of the spleen has been thought to be an important object of TREATMENT, under the supposition that the leucocythæmia will be diminished in proportion. With reference to this object, various measures have been employed—namely, quinia in full doses, hypodermic injections of ergotin, the iodide of potassium, the cold douche, ice applied over the spleen, and the application of electricity. Each of these measures has appeared in some cases to have produced in a limited degree the desired effect, but in other cases to be useless. It cannot be said that clinical experience has established the therapeutic value of any measure employed for the object just stated. Extirpation of the spleen has been resorted to in at least 16 cases, in all, save one, with a fatal result, death resulting from either hemorrhage or peritonitis.¹ The liability to fatal hemorrhage is enough to render the operation unwarrantable. Were the operation warrantable, or were it practicable to reduce considerably, by any measure of treatment, the size of the spleen, it is by no means certain that the leucocythæmia would be controlled; the supposed pathological connection between the latter and the splenic enlargement being theoretical. Moreover, the gravity of the disease does not depend on the excess of the white corpuscles in the blood. In pseudo-leucocythæmia and pernicious anæmia, kindred diseases in which there is not a considerable excess of white corpuscles, the gravity is not less than in leucocythæmia.

[Marked success has followed the treatment of leucocythæmia with arsenic, but to obtain good results from this drug it must be pushed to the point of tolerance. By gradually increasing the dose of Fowler's solution it may be given to the extent of 25 drops three or four times daily. Under such doses the skin of the patient is apt to assume a bronzed hue which is especially marked upon the abdomen and over the bony prominences, such as those of the tuber ischii and the spine of the scapula.

Kirnberger, Sticker, DaCosta, Hershey, and others have observed improvement to follow the inhalation of oxygen, and this measure should be thoroughly tried before regarding the case as hopeless.

Mosler recommends the employment of the oil of eucalyptus, which he administers in pill with piperin and quinia.—H.]

The remaining measures of treatment consist in meeting symptomatic indications, and adopting means, medicinal and hygienic, which may succeed in arresting the progress of the disease, improving the general condition of the patient, and prolonging life. These objects of treatment will embrace the prolonged use of preparations of iron, the various tonics which are likely to improve appetite and promote digestion, hæmostatic remedies and appliances, an alimentation as abundant and nutritious as possible, cod-liver oil as a nutrient, favorable climatic influences, out-of-door life, mental diversion, and all available sanitary measures with reference to nutrition and general invigoration.

¹ One successful case of extirpation of the spleen in leucocythæmia has been reported in Italy.

CHAPTER III.

PSEUDO-LEUCOCYTHÆMIA—HODGKIN'S DISEASE.

PSEUDO-LEUCOCYTHÆMIA is the name of an affection in which anatomical changes similar to those in leucocythæmia are present, without an increase of white corpuscles in the blood. In many cases the anatomical changes are apparently identical in both diseases. In such cases it seems unscientific to make one symptom—namely, the presence of an excess of white corpuscles—the basis of classification. In justification of this, however, it may be said that the difference in the state of the blood not improbably depends upon anatomical conditions which have not yet been recognized. Lymphatic, splenic, and perhaps medullary varieties may be distinguished in pseudo-leucocythæmia upon the same grounds as in leucocythæmia. In the majority of cases the lymphatic glands are primarily and most extensively involved. Hence the lymphatic form is the one generally meant when the term pseudo-leucocythæmia is used without qualification. A medullary variety has not been recognized generally, but certain cases of progressive pernicious anæmia probably belong to this subdivision. To these reference will be made in the next article. In splenic pseudo-leucocythæmia the spleen is the part mainly affected. This variety has been called also splenic anæmia and simply hypertrophy or tumor of the spleen. It is not to be confounded with the chronic enlargement of the spleen due to malarial infection. In splenic pseudo-leucocythæmia the lymphatic glands are usually, if not always, involved, but to a less extent than in the lymphatic variety of the disease. As the affection of the spleen and that of the lymphatic glands are usually combined, it is no more possible to draw a sharp line of distinction between the splenic and the lymphatic variety than between the same forms of leucocythæmia. While the splenic variety of leucocythæmia is much more common than the lymphatic, the reverse is true in pseudo-leucocythæmia. The anatomical changes in the spleen are similar to those in leucocythæmia, and need not be again described. A nodular enlargement of the Malpighian follicles is more frequent than in leucocythæmia.

The following names are in use to designate the lymphatic or most frequent variety of pseudo-leucocythæmia: Hodgkin's disease,¹ adenia (Trousseau), lymphatic anæmia (Wilks), malignant lympho-sarcoma (Langhans), malignant lymphoma (Billroth), and lymph-adenosis (Ranvier, Gowers). The name pseudo-leucocythæmia was introduced by Cohnheim. It is probable that a number of different pathological conditions have also been described under these names, especially the term lympho-sarcoma. Scrofulous enlargements of the lymphatic glands, enlargements confined to a single group of glands, and the rare cases of primary sarcoma beginning in one group of glands and forming metastases in various parts of the body, but not by preference in other lymphatic glands, are to be excluded from the disease under consideration. In this affection several groups of glands, sometimes nearly all in the body, are involved. In a large proportion of cases the spleen and the liver are enlarged. Secondary deposits may be present in most parts of the body.

¹ Hodgkin published his observations in 1832 (*Medico-Chirurgical Trans.*, vol. xvii. p. 69), before leucocythæmia was known. He first called attention to coincident enlargement of the spleen and of the lymphatic glands as a distinct disease. His description included, undoubtedly, cases both of leucocythæmia and of pseudo-leucocythæmia. Some writers apply the name Hodgkin's disease to lymphatic leucocythæmia as well as to pseudo-leucocythæmia.

The change in the lymphatic glands consists in an increase of the cells and of the reticulum. Virchow and later writers distinguish two forms of lymph-adenoma, the soft and the hard. In the soft variety the glands are large, soft, almost fluctuating, of a gray or reddish-gray color, and often filled with ecchymoses. The enlargement is due to a new growth of lymphoid cells, between which is a delicate reticulum with wide meshes. In the hard form the consistence of the swollen gland is firm, the color grayish or yellowish-white, and with the hyperplasia of the cells there is a new growth and a thickening of the reticulum or stroma, denser and more marked than in the soft lympho-sarcoma. There are transitional forms between the hard and the soft variety. In many cases the hard is a later stage of the soft enlargement. In the same case the characters are not always uniform. Some glands may be hard and others soft. It is therefore not desirable to make a sharp distinction between hard and soft lymph-adenoma, although there are undoubtedly cases in which the hyperplasia of the reticulum predominates from the onset, the glands in no stage of the affection having been soft. It is the soft variety which corresponds more closely, in the anatomical appearances of the lymphatic glands, with leucocythæmia. The enlarged glands may reach the size of a hen's egg. They may remain distinct or may become compacted together into a nodular mass, in which the individual glands can no longer be distinguished. In the latter case there has been either a periadenitis or an extension of the lymphatic growth into the capsule of the gland and into the surrounding connective tissue. The skin over the swollen glands is, as a rule, freely movable, rarely adherent. Upon section of the glands the normal distinction between cortex and medulla is usually obliterated. In the harder tumors, often shining and more or less hyaline masses of fibroid tissue may be detected. Fatty and caseous degenerations are very rare, a circumstance which distinguishes lymph-adenomatous from serofulous enlargements. The affection begins oftenest in the cervical glands. It has a tendency to involve especially the glands along the great vessels; hence, the retro-peritoneal glands are more frequently affected than the mesenteric. The starting-point of the disease may be in the mediastinal glands.¹ The affection may remain for a considerable time stationary in one group of glands without impairment of the general health, and then rapidly increase and become generalized, with the development of marked cachexia. The glands may attain a large size without making compression upon surrounding blood-vessels, but in some cases there are severe symptoms resulting from pressure on the vessels, the air-passages, etc.

The spleen is enlarged, according to Gowers, in four-fifths of the cases. The increase in size may be enormous, but, as a rule, it is much less than in leucocythæmia. In the smaller number of cases the appearance is that of a diffuse hypertrophy of the splenic pulp; in the majority there are disseminated whitish growths in the form of nodules throughout the spleen. These are probably hypertrophied Malpighian follicles and growths in the periarterial sheaths. Infarctions may be observed as in leucocythæmic spleens. In the liver there may be lymphoid nodules or a diffuse infiltration of the interlobular tissue with lymphoid cells. In the latter case grayish streaks surround the acini. The hepatic capillaries may be distended with blood. As pointed out by Schulz, the secondary lymphoid formations in the different parts of the body involve especially the walls of the vessels. These secondary growths

¹ R. Schulz (*Arch. d. Heilkunde*, Jahrg. 15, p. 223, 1874) has analyzed 38 cases with reference to the frequency with which different groups of glands are affected. The cervical glands were affected in 28 cases, the retro-peritoneal in 21, the inguinal in 20, the mediastinal in 18, the bronchial in 14, the mesenteric in 14, the lumbar in 12, the axillary in 9, the cubital in 4, the popliteal in 1.

have been met with in nearly all parts of the body, as the kidneys, the serous membranes, the testicles, the lungs, the brain, the retina, the skin, etc. The thymus, the solitary follicles, and Peyer's patches may be diseased, as in leucocythæmia. The marrow of the bones may present a reddish appearance, as in pernicious anæmia, and may contain lymphomata. It rarely shows the pvoid alteration found in leukæmia.

We are at present unable to explain the relations between pseudo-leucocythæmia and leucocythæmia. We do not know why apparently identical changes in the lymphatic structures should be attended in one case by increase of white corpuscles in the blood, and not in another case. The theory that in pseudo-leucocythæmia there is some obstacle to the passage of cells from the hyperplastic lymphatic glands into the blood- or lymph-current is plausible, but is not supported by any anatomical facts. Ackermann¹ has succeeded in injecting the afferent and the efferent lymphatic vessels of both the soft and the hard glands. He finds them pervious. The fact that there may be the same changes in the spleen, lymphatic glands, and in other parts in pseudo-leucocythæmia as in leucocythæmia is evidence against the view of those who hold that in leucocythæmia these changes are the result of a primary increase of white corpuscles in the blood. In some cases, especially of hard lymph-adenoma, the origin of the growth appears to be local; but in the majority of cases several groups of glands are affected simultaneously or in rapid succession. In such cases a primary dyscrasia is assumed to exist.

The SYMPTOMATOLOGY of lymphatic pseudo-leucocythæmia embraces the events which belong to the clinical history of leucocythæmia—namely, general debility, feebleness of the circulation, hemorrhages, general dropsy, pleuritis, and other complications, together with the varied phenomena referable to persistent progressive anæmia. A distinctive feature is the occurrence, uniformly earlier and more extensive, of enlargement of lymphatic glands, and often the development of lymphoid tumors where these glands are not normally discoverable. The cervical glands are affected in a great majority of cases, and in most of these cases primarily. The aggregated enlarged glands may attain to a large size, causing much deformity. Next in frequency the axillary glands are affected. The glands in the anterior and posterior mediastinum, the bronchial, the cardiac, the retro-peritoneal, the mesenteric, and the inguinal glands, may be, severally or collectively, the seats of the local affection. Lymphatic growths may be found in the tonsils, the thorax, the soft palate, the posterior part of the tongue, the œsophagus, and beneath the skin. Perhaps the most remarkable case on record as regards the extensive distribution of these growths or tumors was reported by Dr. James H. Hutchinson.² In this case, exclusive of enlarged cervical glands, of a tumor of the size of a hazel-nut on the upper eyelid, and of a large tumor involving the sternum and the anterior mediastinum, two hundred and thirty-nine tumors, ranging in size from that of a small pea to half a walnut, were counted on the surface of the body. There were twenty tumors on the surface of the brain. A tumor surrounded the bodies of the sixth, seventh, and eighth dorsal vertebræ, and extended within the spinal cord, causing complete paraplegia. Three hundred small tumors were counted within the lungs. Small tumors were scattered over the peritoneal covering of the intestines. It is noteworthy that in this case the spleen and liver were healthy. An unusual feature was the existence of intracranial lymphatic growths.

The pressure of the tumors in different situations may give rise to important symptoms. Pressure upon the larynx or trachea may obstruct respiration, and death is sometimes due to suffocation. Paralysis of the laryngeal muscles

¹ "Ueber die malignen Lymphome," *Diss. Bern.*, 1879.

² Vide *Trans. College of Physicians of Philadelphia*, 3d Series, vol. i., 1875.

may be caused by pressure upon the recurrent laryngeal nerves. Obstruction of the bronchi may be caused by enlarged bronchial glands. The heart is sometimes dislocated. The œsophagus in rare instances is obstructed. The cervical tumors may diminish the arterial supply to the brain by pressing upon the carotids, or they may induce venous congestion by pressure upon the jugular veins or the vena cava. Deafness is not infrequently produced by growths within the pharynx. The pneumogastric nerve may be involved in a tumor, and the action of the heart be thereby retarded. Pain in the upper or lower extremities may result from pressure upon the nerves in the axillary and inguinal regions. The femoral vein may be compressed and œdema of the lower limb follow. Jaundice is sometimes attributable to pressure upon the bile-duct. Gastric disturbances and diarrhœa may be symptomatic of lymphoid growths in the stomach and intestines.

The *duration* of pseudo-leucocythæmia, like that of leucocythæmia, varies from a few weeks to many years. Of 42 cases analyzed by Dr. Hutchinson, in 29 death took place within two years, and in 34 within three years. The average duration is a little less than that of leucocythæmia.

As regards *CAUSATION*, as little is known of this disease as of leucocythæmia. In the larger number of cases the age is between ten and thirty years, but the disease sometimes occurs in childhood and in extreme old age. A decided influence pertains to sex, a large majority of patients being males. An etiological agency referable to antecedent diseases or to habits of life or to any appreciable morbid influences has not been established. The disease often occurs in persons who at the time of its development apparently were perfectly well.

The *DIAGNOSIS* of lymphatic pseudo-leucocythæmia is based upon symptoms common to this disease and to leucocythæmia, taken in connection with the affection of the lymphatic glands and the fact that there is not an increase in the white corpuscles of the blood sufficient to constitute the leucocythæmic condition. The affected lymphatic glands do not undergo the processes of necrosis and suppuration which characterize scrofula; nor are there the gradual invasion of adjacent parts and the ulcerations which characterize the local history of carcinoma. [A diagnostic mark of lymphatic pseudo-leucocythæmia is the free movement upon each other of a group of enlarged glands, the sensation of which has been compared by Southey to that of balls in a net. This free mobility is absent in sarcoma, of which the small round-celled form is almost morphologically identical with the enlargement of lymphatic pseudo-leucocythæmia.—H.]

The *PROGNOSIS* is no better than in cases of leucocythæmia. The supposed instances of recovery in an early stage are open to the suspicion of an error in diagnosis. There are probably very few if any exceptions to the rule of a fatal termination when the disease is so far advanced that the diagnosis is positive. The progress of the disease may be either slow or rapid. It is rapid in cases with pyrexia, profuse hemorrhage, and considerable anasarca. The extent of the distribution and the degree of the glandular growths constitute a measure of the tendency to a rapid progress. The immediate cause of death may be an important complication, such as disease of the kidneys, purulent pleuritis, etc. The pressure of the tumors on important parts may lead to the fatal ending. Irrespective of these causes, the disease proves fatal by slow asthenia.

Measures of *TREATMENT* have been directed especially to the affected glands. The external application of iodine, the employment of cold and heat, frictions, blisters, the injection into the tumors of iodine, nitrate of silver, carbolic acid, arsenic, and other topical remedies, and galvano-puncture, have all been tried, with but little if any satisfactory result. Excision of the affected

glands has been repeatedly resorted to, but the efficacy of this measure has not been established. The removal of the tumors or their dispersion by any local treatment would not strike at the root of the disease. An unknown essential pathological condition underlies the affection of the glands. This condition cannot be reached by any therapeutical appliances as yet ascertained. Excision, however, of enlarged glands may be advisable with a view to relieve parts, such as the larynx or trachea, sensory nerves, etc., from pressure. The internal use of arsenic, the doses increased to the utmost limit of toleration, and conjoined with the injection of Fowler's solution into the affected glands, has been advocated by Winiwarter as a useful method of treatment. [Warfvinge has also reported success from the latter method—i.e. from the intrasplenic and intraglandular injection of Fowler's solution. Four drops was the dose invariably employed by him. Under this treatment the splenic and glandular swellings diminished rapidly in size, and no unpleasant results attended or followed the injections.—H.]

Aside from any treatment instituted with the hope of effecting a cure, the objects and the measures are those stated in connection with leucocythæmia.

CHAPTER IV.

PERNICIOUS ANÆMIA.

THE name pernicious anæmia is given to a severe, often fatal, form of anæmia for which we are unable to assign a sufficient cause either before or after death. The disease has also been called idiopathic or essential anæmia. This form of anæmia was first described by Walter Channing of Boston in 1842. Subsequently, Addison described idiopathic anæmia clearly and concisely. Since Biermer's publication upon progressive pernicious anæmia in 1872 special attention has been directed to this disease.

Pernicious anæmia may develop without any apparent cause, in persons previously healthy and in good hygienic surroundings. More frequently it is secondary to conditions which ordinarily impair the health or produce simple anæmia. Thus, pernicious anæmia has been observed especially among those poorly housed, scantily clad, or imperfectly nourished; and also during or after pregnancy, particularly after repeated pregnancies. Further causes which have been noticed are—exhausting discharges, such as diarrhœa, repeated hemorrhages, mental anxiety, and excessive mental or physical exertion. The disease has been observed to follow typhoid fever. Endemic influences have also been thought to be of some importance in the etiology of this disease. An unusually large number of cases has been reported from Switzerland and certain parts of Germany. In this country it seems to be less common, although it is by no means a rare disease. Excluding cases dependent upon child-bearing, pernicious anæmia is as common among men as among women. The disease is rare before twenty or after sixty years of age.

It is important to note that the causes which have been mentioned, although they may explain a certain amount of anæmia, do not account for the pernicious character of the anæmia. To explain this, it is necessary to assume a profound disturbance of the blood-forming organs—a disturbance

which may be either an excessive destruction or a lessened production of the red blood-corpuscles, or both.

An anæmia as intense as pernicious anæmia may develop in connection with certain structural diseases, such as malignant tumors, chronic Bright's disease, phthisis, leucocythæmia, pseudo-leucocythæmia, syphilis, chronic malaria, chronic diarrhœa, and the presence in the intestine of the parasites *Anchylostomum duodenale* and *Bothriocephalus latus*. The anæmia in these cases is symptomatic, whereas it belongs to the conception of pernicious or idiopathic anæmia that no adequate cause can be found to explain the anæmia.

It may happen that the exclusion of some of the structural conditions named is not easy or even possible during the life of the patient; and upon post-mortem examination they may escape detection or their recognition may depend in an unusual degree upon the knowledge and skill of the pathologist. Hence it is that a certain amount of uncertainty surrounds the diagnosis in many cases of pernicious anæmia. Thus, it has repeatedly happened that a case supposed during life to be an instance of pernicious anæmia has proven upon post-mortem examination to be one of latent cancer of the stomach. A whole group of cases once supposed to belong to pernicious anæmia, and described as tropical chlorosis and as the anæmia of workers in tunnels, has been found to depend upon the presence of the *Anchylostomum duodenale*. A certain number of cases with all of the symptoms of pernicious anæmia has been proven to depend upon degeneration of the gastric tubules, thus establishing a mode of causation of profound anæmia which was suggested by the author as long ago as 1860.¹ It is probable that certain other obscure forms of profound anæmia, which now receive a provisional shelter under the name of pernicious anæmia, will be relegated by future investigations to other categories.

The most important of the ANATOMICAL CHANGES in pernicious anæmia relate to the blood. It is probable that in many cases there is a diminution in the quantity of blood out of proportion to the reduction in the weight of the body. Such a true oligæmia was proven by Quinke to exist in two of his cases. A diminution in the mass of blood, however, is usually more a matter of inference than susceptible of actual proof. An essential change in this disease is the loss of red blood-corpuscles, or oligocythæmia, which may be accurately estimated by means of the hæmacytometer. The blood appears abnormally pale. In pernicious anæmia the number of red corpuscles may be reduced to one-third or even one-tenth of the normal amount. Instead of 5,000,000 red corpuscles per cubic millimetre, it is common to find no more than 1,500,000. The number is exceptionally reduced to 500,000 or even lower. The quantity of hæmoglobin is not always reduced in proportion to the diminution of red blood-corpuscles, so that the actual degree of anæmia may be less intense than is indicated by simply counting the corpuscles. It is considered by Laache as somewhat characteristic of pernicious anæmia, in contrast with chlorosis, that the percentage of hæmoglobin in the red blood-corpuscles is greater than normal. There may, however, be extreme reduction in the quantity of hæmoglobin, as in a fatal case reported by Quinquaud, in which the percentage of hæmoglobin was 2.6 (instead of the normal 12 to 14). More commonly than in any other form of anæmia, the red blood-corpuscles present abnormalities in size and in shape. There may be large corpuscles, 12 to 14 μ in diameter, as well as small corpuscles less than 6 μ in diameter. There are frequently diversities in form described under the name "poikilocytosis" such as pear-shaped, ring-shaped, cup-shaped, kidney-shaped corpuscles, corpuscles with tail-like processes, etc. There may be alterations in the

¹ Austin Flint, *American Medical Times*, 1860.

composition of the red blood-corpuscles revealed only by certain staining reagents. Nucleated red blood-corpuscles are sometimes—according to Ehrlich usually—present. Blood-plates are generally fewer than normal. The white blood-corpuscles are usually not increased in number, but there have been a few curious cases observed in which a sudden invasion of the blood with large numbers of leucocytes occurred, so that the pernicious anæmia became an actual leucocythæmia.

The specific gravity of the blood is reduced in consequence of the diminution in solid constituents. In one case Quinke estimated the specific gravity at 1028, instead of the normal 1055.

The body is, as a rule, not emaciated, and there may be decided obesity. The surface of the body and the various organs and tissues are extremely pale. Small extravasations of blood are usually found in different parts. The most frequent seats of ecchymoses are the retina, the inner surface of the dura mater, and the serous membranes. The hemorrhages in the retina are usually small. They are most frequent near the papilla and along the vessels. The ecchymoses in the retina often present a whitish or grayish centre. More or less general œdema, with dropsical accumulations in the serous cavities, is common. There may be a slightly jaundiced tint of this fluid as well as of the sclerotic coat and of the integument.

Almost without exception in the fatal cases of pernicious anæmia there is more or less fatty degeneration of the heart. Often this degeneration is extreme and extends throughout the whole thickness of the heart. The heart-walls are usually flabby. Fatty degeneration of the hepatic and of the renal epithelium has also been observed.

The spleen may be unchanged or it may be moderately swollen. The lymph-glands, which are usually normal in appearance, may be somewhat swollen and of a deep-red color, containing an unusual number of red blood-corpuscles, among which may be nucleated red corpuscles.

An interesting lesion of pernicious anæmia is a large accumulation of iron or some ferric compound in certain organs of the body, especially in the liver, the spleen, the kidneys, and the marrow of the bones. If microscopic sections of these organs be treated with sulphide of ammonium, a great quantity of greenish-black granules of sulphide of iron can be seen in the cells. Thus, the hepatic cells may appear thickly studded with such granules. This accumulation of iron points to an enormous destruction of red blood-corpuscles, for the iron is doubtless derived from this source.

[It was at one time supposed that the iron in the liver was derived from that administered to the patient, but it has been clearly proved that this is not the case. The amount of iron in the liver appears to be practically uninfluenced by the medicinal administration of this substance. The demonstration of an excess of iron in the liver in cases of pernicious anæmia was first made by Quinke, but his observations do not seem to have attracted the attention which they undoubtedly deserved. This was partly due to the fact that he was not positive in his opinion as to the source of the iron. He thought it might have been derived from preparations of that metal administered to the patient. In 1888, Dr. W. Hunter, in a series of articles in the *British Medical Journal*, not only confirmed Quinke's discovery, but showed that the iron in the liver is deposited in a special manner, being contained, for the most part, in the liver-cells, and especially in those of the outer and middle zones of the acini. The central cells are generally in a state of fatty degeneration and atrophy, and often fail to give any iron reaction. In Hunter's opinion, which is based upon the most careful experimentation, the seat of blood-destruction is "chiefly the portal circulation,

more especially that portion of it contained within the spleen and liver, and the destruction is effected by the action of certain poisonous agents, probably of a cadaveric nature, absorbed from the intestinal tract."

Hunter has also called attention to the dark color of the urine in pernicious anæmia, and has proved it to be due to the presence of pathological urobilin, a substance known to be derived from the disintegration of hæmoglobin.

The proofs in favor of the view that pernicious anæmia is associated with increased hæmolysis are certainly convincing, but it is going too far to say that the disease presents no evidence of imperfect hæmogenesis. The large, flabby, misshapen red corpuscles of pernicious anæmia certainly present anything but a healthy aspect. In addition, numerous nucleated red corpuscles are often present in the blood of pernicious anæmia, and everyone acknowledges such corpuscles to be embryonic. Again, the red corpuscles of pernicious anæmia are often possessed of amœboid movement—a fact to which attention has been called by Hayem, and which I myself have observed. This property is characteristic of a lower order of cells, the leucocytes. Finally, Rindfleisch, who has made a careful study of the marrow in two cases of pernicious anæmia, concludes that the disease is due to defective hæmogenesis. He bases this opinion upon the absence of elements which he and others regard as transition forms between the red nucleated marrow-cells, which were unusually large and abundant in his cases, and the fully-developed red corpuscles.

In view of the above-mentioned facts it seems to the writer that the evidences of defective hæmogenesis in pernicious anæmia are at least as strong as those of increased hæmolysis.—H.]

In the great majority of cases of pernicious anæmia, although not invariably, the fatty marrow which is normally present in the long bones of adults is changed into red or lymphoid marrow. Microscopic examination of the altered marrow shows that the fat-cells have in great part disappeared, and have been replaced by large and small, coarsely and finely granular, medullary cells. In addition, as first pointed out by Cohnheim, there are often nucleated red corpuscles in considerable number, which would seem to indicate an increase in the blood-forming function of the marrow. Cells containing red corpuscles or their fragments are often found in large number both in the marrow and in the spleen. In a few cases there has been observed a change in the marrow resembling the pyoid alteration of leucocythæmia. Also in a few cases lymphomatous growths have been found in the marrow of the bones, in the periosteum, and in the kidney.

These changes in the marrow have led to the idea that at least some cases of pernicious anæmia may be regarded as the myelogenic form of pseudo-leucocythæmia. This view is probable, but an objection to it is that similar changes, although generally less intense, are often present in severe symptomatic anæmia.

The anatomical changes found after death from pernicious anæmia are not peculiar to this disease, but may be present in profound anæmia from any cause. Nor do these changes explain the pathogeny of the anæmia. As already mentioned, the high percentage of iron found in different organs is evidence of abnormally great destruction of red blood-corpuscles, although nothing is known as to the cause of this destruction.

The SYMPTOMS of pernicious anæmia, in so far as they represent a profound and persistent anæmic condition, are essentially those belonging to the clinical history of the grave hæmatopoietic diseases already considered—namely, leucocythæmia and pseudo-leucocythæmia. Anorexia, nausea, and vomiting are

symptoms more constant and prominent than in the diseases just named. More than twenty-five years ago, I ventured to predict that the disease would be found to involve degenerative changes in the gastro-intestinal tubules. In a certain number of cases this prediction has been found to be correct. (See p. 369.) In respect of the symptomatology it will suffice to state the points embraced in the diagnosis.

The liability to the error of mistaking for pernicious anæmia that which is symptomatic of some obscure, grave local affection, especially carcinoma, has been already mentioned. This error cannot always be avoided. Investigations, however, should always be directed to the discovery of some local affection adequate to explain the anæmia. A positive diagnosis requires the exclusion of any such affection. A diagnostic point bearing on this inquiry relates to the nutrition of the patient. Addison called attention to the fact that in the cases of idiopathic fatal anæmia which he described emaciation was not marked, considerable embonpoint being often maintained. As a rule, it is otherwise when anæmia is symptomatic of a grave affection like carcinoma. In some cases of pernicious anæmia, however, there is extreme emaciation.

Leucocythæmia is excluded by the absence of the characteristic blood-change expressed by the name. The white blood-corpuscles are not in sufficient excess to denote that disease. Pseudo-leucocythæmia is excluded by the absence of the affection of the lymphatic glands which characterizes the disease generally understood by that name, more commonly known as Hodgkin's disease.

The question arises not infrequently in cases of simple anæmia and chlorosis, in which the anæmic condition is unusually intense and rebellious, whether the anæmia be not pernicious. As bearing on this question the following points are to be considered: An adequate discoverable causation renders it probable that the anæmia is benign. Yet an anæmia traceable to causes which seem to be adequate may prove to be pernicious. Intractability of the disease after the removal of supposed causes and the faithful employment of appropriate measures of treatment is proof of a pernicious character. Certain events belonging to the clinical history of pernicious anæmia rarely occur in benign anæmia and chlorosis, however protracted. These events are hemorrhages in different situations, general dropsy, and pyrexia. Pyrexial paroxysms of greater or less intensity, of variable duration, and irregular in their occurrence are frequent in pernicious anæmia, as they are also in leucocythæmia and pseudo-leucocythæmia. The loudness of the hæmic murmurs—cardiac, arterial, and venous—is somewhat diagnostic of pernicious anæmia. Notable feebleness of the heart's action, pointing to fatty degeneration, has diagnostic significance. Age is to be taken into account; in the majority of cases pernicious anæmia affects persons in the middle period of life, whereas chlorosis in a large proportion of cases affects young subjects. It remains to be determined by clinical observations how much can be inferred from the abnormal appearances of the red corpuscles as regards the diagnosis. Impaired vision dependent on retinal ecchymoses is to be included among the diagnostic points, as well as the existence of ecchymoses without an appreciable impairment of vision. The employment of the ophthalmoscope is thus of importance with reference to the diagnosis. According to Quincke, ecchymotic spots in the retina are so frequent in pernicious anæmia, and so rare in other affections involving anæmia, that they have a significance almost pathognomonic. That author has also called attention to the occurrence in some cases of a systolic pulsation of the superficial cervical veins without venous turgescence. Func-

tional insufficiency of the tricuspid valve is the probable explanation of this sign, which occurs sometimes temporarily in other connections.

The PROGNOSIS is affected materially by the latitude of the signification of the term pernicious in this application of it. If a fatal termination be essential for the disease to be considered as pernicious, of course there is no possibility of recovery. This is an extreme view. It suffices for the application of the term pernicious that the anæmia present an *ensemble* of the characters which distinguish it in the cases which do prove fatal. Cases have been reported presenting the requirements for the diagnosis of pernicious anæmia in which recovery has taken place. Taking the view just stated, Biermer and Quincke report 6 recoveries out of 54 cases, and Pye-Smith has collected 20 cases of recovery.

The DURATION of fatal cases varies from a few weeks to several months. The average duration is less than that of leucoeythæmia and pseudo-leucoeythæmia. Sudden death sometimes occurs from syncope. Cerebral hemorrhage may be the immediate cause of death. If the disease be developed during pregnancy, abortion or miscarriage takes place, the patient speedily dying. If death be not caused by either cerebral hemorrhage or syncope, the mode of dying is by slow asthenia.¹

The objects and general principles of TREATMENT are sufficiently obvious. The removal of all causes which may have produced the disease or which render it persisting and progressive is an object of prime importance. The substitution for these causes of all agents and influences which affect favorably the functions concerned in assimilation and nutrition is the next important object. These objects are widely comprehensive, but it is not necessary to go into details. The same principles are involved as in the treatment of the anæmia in all the grave diseases affecting the hæmatopoietic system. Of medicinal remedies, arsenic has been found to be the most valuable, and should always be given a trial.

[Dr. Byrom Bramwell of Edinburgh was the first to employ this drug systematically in the treatment of pernicious anæmia. Of eight cases reported by him in the *Edinburgh Medical Journal*, 1877, he treated three with arsenic, and they all recovered. Following his example, Dr. Finny treated three cases with arsenic, two of which recovered. In numerous other cases arsenic has been of decided benefit. Iron is of little avail, as a rule, in this disease—another point in which the latter differs decidedly from chlorosis. Iron often disagrees with the patient on account of the irritable state of the stomach, and only the blandest preparations should be prescribed at first. In a case at the Episcopal Hospital of Philadelphia a few years ago, in which every symptom of pernicious anæmia was present, recovery followed the employment of dialyzed iron.

Transfusion has been employed in a number of cases, and with variable results. In cases which resist the ordinary measures of treatment it should be resorted to. Like the operation of tracheotomy, the tendency is to postpone it until the patient is in a hopeless condition. Brakenridge has recently reported to the Medico-Chirurgical Society of Edinburgh five cases of pernicious anæmia treated by transfusion of blood, in three of which marked improvement followed each operation, while in "some" the red cells rapidly rose to the normal number and the patients were practically cured. The transfused blood was mingled with a solution of sodium phosphate to prevent coagulation. Subcutaneous injections of defibrinated blood have also been successfully employed. The injections should be performed under

¹ For a full report of three cases, and an analysis of the cases published in America (39), vide article by Dr. J. H. Musser in *Proceedings of the Philadelphia County Medical Society*, 1885.

strict antiseptic precautions, and the amount of each should be from 20 to 40 grammes. Inhalations of oxygen and subcutaneous injections of quinine have been recommended by Henrot of Rheims, France. Of equal importance with drugs is a nutritious, easily-digestible diet. In case of great irritability of the stomach nutritious enemata of peptonized milk and eggs should be administered.]

CHAPTER V.

ADDISON'S DISEASE.

[IN the year 1855, Dr. Thomas Addison¹ described an affection characterized by disease of the suprarenal capsules, by a peculiar discoloration of the skin and of certain mucous membranes, and by the development of progressive and fatal asthenia. This disease, in honor of its discoverer, is called usually *Addison's disease*. It has also received the names *bronzed-skin disease*, *melasma suprarenale*, and *suprarenal capsular disease*. Since the masterly description given by Addison little has been added to our knowledge of this disease, which still remains one of the most obscure in the nosology. The most important addition since Addison's memoir is that the change in the suprarenal capsules usually presents certain well-defined anatomical characters common to the great majority of cases. It was thought by Addison that any disease of the suprarenal capsules was capable of producing the characteristic group of symptoms; it is now known that, as a rule, the morbid process in the capsules is a definite one, to which the name fibro-caseous metamorphosis is applicable.

Almost without exception both suprarenal capsules are involved. The change may be farther advanced in one than in the other. The capsules are usually found to be enlarged, of firm consistence, and with nodulated surfaces. The size may equal that of a small hen's egg, but it is usually less. Sometimes the size is normal or even less than normal. The latter condition generally corresponds to a late stage of the process. Upon section, usually no trace of the normal parenchyma or of the distinction between cortex and medulla can be detected. The place of the normal tissue is occupied by opaque, yellow, friable, cheesy masses imbedded in firm, grayish, semi-transparent fibrous tissue. The proportion between these two substances varies; sometimes one predominates and sometimes the other. On close inspection gradual transitions from the grayish fibrous to the yellow cheesy material can often be seen. The caseous substance may become dry and calcified, or it may soften and form collections of thick, creamy fluid resembling abscesses. The whole interior of the organ may be converted into a hard, cretaceous mass, or into a cavity containing creamy fluid. In this case the organ may be much diminished in size. In some cases small grayish granulations resembling miliary tubercles can be seen around the cheesy material and in the fibrous stroma. The microscopical examination of the gray fibrous material shows a fibrillated, sometimes a reticulated, stroma containing fusiform cells, lymphoid cells, and not infrequently giant-cells. The caseous substance con-

¹ *The Constitutional and Local Effects of Diseases of the Suprarenal Capsules*, London, 1855.

sists of a granular detritus of albuminous and some fatty particles with remnants of cells. Little nodules composed of lymphoid cells and giant-cells in other words, of tuberculous tissue—have been occasionally observed. As to the nature of this change in the suprarenal capsules writers are not agreed. Some consider it as a chronic inflammation resulting in the formation of connective tissue and in caseation of the inflammatory products (Wilks). Others regard the alteration as tuberculous in character. This is the most probable view. In not a few cases undoubted tuberculous changes have been found at the same time in the lungs and in other parts of the body, but there have been many cases in which the alteration was confined to the suprarenal capsules. In some cases tubercle bacilli have been found in the lesions of the suprarenal capsules; in other cases the bacilli have been missed. Further observations upon this point are needed, as well as concerning the inoculability in animals of the caseous substance in the capsules.

The altered capsules are usually found imbedded in a mass of indurated fibrous tissue which binds them firmly to surrounding structures, such as the liver, pancreas, kidneys, stomach, vena cava, and diaphragm. This overgrowth of connective tissue generally invades the important sympathetic nerves in the neighborhood of the suprarenal capsules—namely, the solar and suprarenal plexuses and the semilunar ganglia. Changes have been found although not constantly, in these nervous structures. These consist in hyperæmia, swelling in consequence of thickening of the nerve-sheaths, fatty degeneration and atrophy of the nerve-fibres and ganglion-cells, and increased pigmentation of the ganglion-cells. Alterations have been described also in the nerve-plexuses in the stomach and in the intestine.

The mesenteric glands, especially those in the neighborhood of the suprarenal capsules, are often enlarged and sometimes cheesy. It is not unusual to find enlargement of the solitary and agminated follicles of the intestine. In some cases the spleen has been found enlarged and softened. Tuberculous deposits in various parts of the body are frequent. Indurated and caseous nodules in the apices of the lungs seem to be the rule. General pulmonary tuberculosis is less frequent. Caseous nodules have been found in the testes, brain (solitary tubercles), and lymphatic glands. The carious condition of the vertebræ, which has been found several times as a complication with and without lumbar abscesses, probably belongs to the category of tuberculous changes. Acute miliary tuberculosis may result from the invasion of the suprarenal veins by the tuberculous material.

The discoloration of the skin and of certain mucous membranes is due to the deposit of brown or yellowish-brown pigment-granules in the lowest layers of the epithelium. In the skin it is found chiefly in the epithelial cells composing the two or three lowest layers of the rete Malpighii, and is most abundant in the layer next to the corium. Similar pigment-granules are found in the connective-tissue cells beneath the epithelium and about the blood-vessels. The deposition of pigment is in the same anatomical elements as in negro.

In some, but not the majority, of cases fatty degeneration of the heart has been noted, and also parenchymatous degeneration of the heart, liver, kidneys. More or less anæmia is usually present, but the anæmia is rarely intense, and it may be absent. Anæmia is not an essential element of the disease.

Before completing the description of the anatomical characters of Addison's disease it is necessary to add that changes in the suprarenal capsules, other than the fibro-caseous metamorphosis, have been reported as associated with bronzing of the skin and the other symptoms of Addison's disease. Most of these changes have been due either to atrophy or to primary or second

cancer of the capsules. Primary cancer of the suprarenal capsules is very rare, and some of the cases so reported seem to have been in reality fibro-caseous metamorphosis. Secondary cancer is more frequent. In the larger number of cases of carcinoma of the suprarenal capsules no pigmentation of the skin was observed. Greenhow, who has analyzed those cases in which discoloration of the skin was present, comes to the conclusion that the pigmentation did not present the characters typical of Addison's disease. Very positive statements, however, have been made as to the identity of the pigmentation with that in Addison's disease. There are observations which strongly support the view that a variety of morbid processes in the suprarenal capsules may produce the symptoms of Addison's disease. On the other hand, apparently typical cases of Addison's disease, so far as the pigmentation and other symptoms are concerned, have been reported without any disease of the suprarenal capsules. In a large number of the cases reported as bronzed-skin disease without change in the suprarenal capsules the pigmentation did not present the typical characters, or it was due to some of the many physiological or pathological causes of discoloration of the skin which have nothing in common with Addison's disease. There remains, however, a small number of cases in which the pigmentation and the constitutional symptoms were the same as those in Addison's disease, but in which the suprarenal capsules were found to be normal.

There has been no explanation at all satisfactory of the relation between the three conditions which characterize Addison's disease—namely, the change in the suprarenal capsules, the pigmentation of the skin, and the constitutional affection. It is not within the scope of this work to enter into a discussion of the different theories which have been proposed. A brief mention of the leading views will suffice to bring out the points at issue. According to one theory, disease of the suprarenal capsules is primary and is the cause of the symptoms. In opposition to this theory it is argued that the symptoms cannot be referred to an abolition of the functions of the suprarenal capsules, whatever those functions may be; for the capsules have been extirpated in animals, and have been destroyed in man by cancer and other processes, without bronzing of the skin or other symptoms of Addison's disease. Nothnagel has succeeded in producing in animals caseous inflammation of the suprarenal capsules without the sequence of Addison's disease. Physiological experiments have shown that these organs are not necessary to life. The theory that the symptoms of Addison's disease are due to irritation of supposed secreting cells in the glands, by which their function is increased and deleterious substances are introduced into the blood, was advanced by Klebs, but is not based on established physiological facts, and has not met with favor. Appreciating the difficulty of referring the symptoms to interference with the function of the suprarenal capsules, many, even of those who regard the disease of the suprarenal capsules as primary, attribute the symptoms to involvement of the adjacent sympathetic nerves and ganglia. This theory is advocated by Virchow, Schmidt, Greenhow, Jaccoud, Resel, and many others. The objections raised against this theory are that the alterations in these nervous structures are not constantly present, that similar changes are found in a variety of processes without any of the symptoms of Addison's disease,¹ and that the affection of the sympathetic does not make any clearer the explanation of the characteristic symptoms. Rossbach believes that Addison's disease is a general neurosis due to functional disturbance of the entire nerv-

¹ Bronzing of the skin has been observed in a few cases of aneurism of the abdominal aorta, and of tuberculous or cancerous disease of the retro-peritoneal glands with involvement of the adjacent sympathetic nerves and ganglia.

system. Another theory is that disease of the suprarenal capsules and its characteristic symptoms are independent of any causative relation to each other, and are all the result of some common antecedent condition which present, Buhl, and others seek in the blood. Buhl suggests the entrance of some morbid agent from without into the blood; in other words, he regards Addison's disease as infectious in its origin. Heschl emphasizes especially the tuberculous diathesis. Pepper ranks Addison's disease with pernicious anaemia, leucocythæmia, and pseudo-leucocythæmia among the anæmotic diseases in which the primary change is a profound disturbance of blood-forming functions.

In a recent paper upon this subject¹ W. Gilman Thompson arrives at the following conclusions: "*First.* That Addison's disease is a condition arising from and dependent upon irritation of the abdominal sympathetic nervous system through lesions of themselves, their ganglia, or diseased suprarenal capsules. *Second.* In the great majority of instances (fully 80 per cent.) the disease originates as a secondary or primary tuberculosis of the adrenals and the sympathetic system is either involved by extension of pathological processes or is functionally disturbed and irritated through the intimate anatomical connection existing between the adrenals and the relatively large number of nerves which they contain. *Third.* Actual lesion of the sympathetic system, while far more common than heretofore supposed, is necessary to produce the varied symptomatic phenomena of the disease, functional disorder, through irritation conveyed from the adrenals, sometimes cause all the symptoms, just as in chorea and many of the convulsions, aggravated hysteria and other functional nervous disorders we are unable to find definite lesions. *Fourth.* In a certain proportion (perhaps over 20 per cent.) the adrenals are affected by some other lesion than those of tuberculosis, or else they remain normal (in 12 per cent.) while the sympathetic nerves and ganglia are alone diseased."—H.]

The following is a description of the appearances of the skin and of the general color, by Dr. Edward Headlam Greenhow, who has devoted a large number of cases to this disease and has analyzed a larger number of cases than have been collected by any other writer:²

The peculiar change of color consists in a gradual darkening of the skin of the face and of the extremities of the body or even of the whole body. The aspect of the face, however, gives to the patient the appearance of belonging to one of the darker races of mankind. Most frequently it has a dusky, smoky, or yellowish color, but sometimes it is of an olive or green-brown color, and sometimes it approaches in parts to the tint of negro skin. The discoloration is more uniform over all parts of the body, but commences earlier and is more marked on some or all of the exposed parts—the face, neck, dorsum of the hands, fingers, and on those parts which are naturally the seat of discoloration on the general surface—the axillæ, abdomen, groins, genital parts, and especially the areolæ. The deep discoloration of the face and of the exposed portions of the body may be regarded as one of the most decisive external signs of the disease, and the appearance of small, well-defined black spots, freckles, or freckles, on already discolored portions of skin is a secondary but no less certain. Although sometimes universal, the discoloration is more frequently only distinctly obvious on certain parts of the body. In the latter cases, however, it probably affects in some degree the entire cutaneous surface, for on microscopical examination the dark spots which by contrast with the dark spots appeared normal

¹ *Transactions of American Physicians*, vol. viii., 1893.

² "On the Pathology of Addison's Disease," *The Lancet*, 1875; also, a memoir on the same subject, *ibid.*, 1876.

have found deposited also in them, though in comparatively small quantity, the pigment which imparts the abnormal color to the skin. The transitions from the darker to the paler shades of the discoloration of different parts of the body are never abrupt; the darkest parts are never sharply-defined patches, but merge insensibly into the lighter or apparently normal portions of the surface. There is, however, one marked exception to this rule. When the skin has suffered any superficial abrasion or injury, or when the patient has been blistered at some recent period, the injured parts not only become much darker than the surrounding portions of the surface, but they present defined margins coinciding with the extent of the cutaneous injury. The cicatrices of deeper injuries, on the contrary, usually remain pale, and are surrounded by a distinct border of more or less dark pigment, contrasting strongly with the ivory-like hue of the cicatricial tissue. It does not, however, require actual abrasion of the skin to excite a greater deposit of pigment in certain parts; slight local irritation of the surface appears in not a few cases to have produced the same effect. I have myself seen dark streaks on the skin corresponding with the lines of pressure exerted on particular parts by petticoat-strings and garters, and the same circumstance has been noted by others. In a case recorded by Mr. Nicholson in 1872 it is stated that the patient, a baker's lad, presented on his shoulders dark stripes corresponding to the bands by which the basket he carried was slung at his back. The discoloration in Addison's disease is not entirely restricted to the skin, being also frequently found upon the mucous membrane of the lips, cheeks, and gums, and also upon the tongue. On the lips it takes the form of an irregular bluish-black streak, running lengthwise, near the junction of the mucous membrane and outer skin. It is seen on the gums and buccal mucous membrane in the form of irregular stains and patches, mostly of a brownish color, with ill-defined margins. In two of my own cases the stains on the buccal mucous membrane have certainly corresponded with seats of irritation produced by the pressure of ragged, protruding teeth; but in other cases I have been unable to verify any such cause. The discoloration of the tongue appears usually in sharply-defined stains of a purplish-black or sometimes inky hue; and in my cases these stains have always been situated near the margins of the organ. On the other hand, the conjunctivæ have always remained normal, and the contrast between their pearly whiteness and the dusky hue of the discolored skin is very striking, and involuntarily recalls the similar contrast in the mulatto or negro countenance.

"We see, therefore, that the discoloration of the skin in Addison's disease usually begins, and eventually becomes deepest, on those parts which are naturally the most liable to become pigmented either by exposure to sun and air or by the excitement of certain physiological processes; and to these must be added such parts as may accidentally be subjected to the excitement of local irritation. In other words, this peculiar change of color is, like many other pathological processes, merely an exaggerated, and therefore a morbid, development of a natural physiological process."

Greenhow describes the constitutional symptoms as follows: "Gradual progressive asthenia, often originating without any apparent cause and seldom dating from any definite period; great languor and indisposition for exertion, with, in advanced cases, breathlessness and palpitation, frequent sighing or yawning, and generally faintness on making any muscular effort, sometimes even on being raised up in bed. There are almost invariably great weakness of the heart's action and remarkable feebleness of pulse; loss of appetite; irritability of stomach, with nausea; and toward the close of the illness at least occasional, and often persistent, vomiting. The mind is generally clear to the last, but so great is the prostration in the latest stages of the disease

that the patient often lies in a drowsy, apparently semi-comatose state, from which, however, he can be roused by questions, and to these he generally gives pertinent, though slow and reluctant, answers. There are in many cases pains in the loins, hypochondria, or epigastrium, and, more rarely, dimness of sight, vertigo, and, near death, a tendency to incoherence or delirium. Death takes place from asthenia, and often rather suddenly." . . . "There is, in uncomplicated cases, comparatively little or no emaciation. The skin is soft and cool. The tongue is usually clean and moist until the last day of life."

The occasional occurrence of convulsions is mentioned by Greenhow, and also by Jaccoud. The convulsions are oftener partial than general. Pye-Smith and others have observed cases which terminated with severe cerebral symptoms—namely, delirium, coma, etc. In a case reported by Nothnagel the coma was associated with acetonuria. Attacks of syncope are not rare, and may end fatally.

All writers dwell upon the frequency and prominence of gastric symptoms—namely, anorexia, nausea with more or less vomiting, eructations, cardialgia, etc.¹ In the early stage of the disease the bowels are generally constipated, but at a later period diarrhœa is not infrequent.

As regards the urine, Thudicum found diminution of uric acid and of coloring matter. Rosenstern ascertained that the excretion of urea is diminished, and that there is an increase of indican.

The course of this disease is progressive, but its progress is not always continuous. Greenhow's observations show, in certain cases, paroxysms of progress, exacerbations, and remissions. During a remission the discoloration of the skin is lessened, and there may be more or less general improvement. Exceptionally, the disease runs a rapid course. In these cases bronzing of the skin usually precedes for some time the constitutional symptoms. In the vast majority of cases the progress is slow, the duration, however, being indefinite, extending sometimes over several months and sometimes over many years, the average duration being a year, or, according to Wilks, a year and a half.

The DIAGNOSIS is to be based on the characteristic bronzing of the skin together with the associated symptoms. A discoloration of the skin bearing more or less resemblance to that of Addison's disease may be referable to pityriasis, chloasma, protracted jaundice, cancerous and tuberculous disease, particularly when seated in the abdomen, the internal use of the nitrate of silver, the permanent staining which follows some syphilitic eruptions, and that caused by exposure, dirt, and the irritation of vermin, the latter described by Voght and by Greenhow under the name "vagabonds' disease." The associated symptoms representing the constitutional affection corroborate the diagnosis as based on the appearances of the skin. It is to be borne in mind that the bronzing of the skin may precede as well as follow the constitutional symptoms. Some delay under these circumstances may be requisite for a positive diagnosis. On the other hand, there is no doubt as to the occasional occurrence of cases of Addison's disease, as proved by the constitutional symptoms and by the characteristic changes in the suprarenal capsules, without any pigmentation of the skin. In these cases generally the duration of the disease has been brief or it has been associated with grave com-

¹ Merkel, author of the article on this disease in *Ziemssen's Cyclopædia*, in a foot-note mentions, "as a curiosity," that in the *Phil. Med. and Surg. Reporter*, June, 1871, an attempt is made to "refer the entire complex set of symptoms to degeneration of the glands of the stomach." If the attempt to connect the disease with glandular organs so vast and important as those which secrete the gastric juice be worthy of being mentioned only as a curiosity, how absurd would it have seemed to the author of that article to refer the disease to organs comparatively so insignificant as the suprarenal capsules had he written his article prior to Addison's researches!

plications. Brown patches in the mouth have been observed without bronzing of the skin. It is not very comprehensible that, associated with pyrexia, the disease should be mistaken for typhoid fever. The author of the article in *Ziemssen's Cyclopædia*, however, states that this mistake was made in a case under his observation. Litten, and more recently Krockner, describe pigmentation of the skin as a sequence of typhoid fever.

Addison's disease resembles the other grave diseases of the hæmatopoietic system in the obscurity of its CAUSATION. It occurs after adult age, in early or middle life, but very rarely in childhood and in advanced age. In a large majority of cases patients are of the male sex, and a majority of these belong to the so-called working class. The character of the anatomical changes, and the not infrequent association with phthisis, justify the conclusion that a tuberculous diathesis may favor the development of the disease.

Writers agree that the PROGNOSIS in the present state of knowledge is fatal, but the duration of the disease sometimes extends over many years. It may remain non-progressive for an indefinite period, and in some cases notable improvement takes place. These are important facts to be considered with reference to the prognosis and as affording encouragement in the treatment.

In the absence of any remedies known to have a special curative efficacy, symptomatic indications are to be fulfilled, and TREATMENT, medicinal and hygienic, is to be pursued with reference to the same objects as in treating the other diseases of the hæmatopoietic system. In a case which came under my observation the treatment by general faradization and galvanization of the sympathetic nerve in the hands of Dr. A. D. Rockwell was accompanied by marked improvement as regards the muscular strength and endurance; the sexual desire and capability, which had been lost, returned, and the bronzing became perceptibly less. This improvement continued for two years, when the patient suddenly, without any apparent cause, failed, and died within twenty-four hours.¹

¹ Vide *Med. and Surg. Electricity*, by Drs. Beard and Rockwell, 2d ed., p. 675. For exhaustive articles in relation to this disease the reader is referred, in addition to the works by Greenhow, to which reference has been already made, to Jaccoud, article "Bronzée maladie," in *Nouveau Dict. de Méd. et de Chirurg. pratique*, tome xi., 1866; and to *Traité de pathologie interne*, tome ii., cinquième édition, 1877; to Averbek, *Die Addison'sche Krankheit*, Erlangen, 1869; to article by Pepper, in *Am. Journ. of Med. Sciences*, April, 1877; to Osler, in *System of Medicine by American Authors*, vol. iii.; and to F. P. Henry, in the *Reference Handbook of the Medical Sciences*, vol. i.

SECTION FOURTH.

DISEASES AFFECTING THE DIGESTIVE OR CHYLOPOIETIC SYSTEM.

CHAPTER I.

DISEASES OF THE TONSILS, THE PHARYNX, THE ŒSOPHAGUS, AND THE PAROTID GLANDS.

Introductory Remarks.—Tonsillitis.—Pharyngitis.—Diseases of the Œsophagus.—Parotiditis.—Mumps.

THE important organs composing the digestive system are the mouth, with the parotid, submaxillary, and sublingual glands, the fauces, the pharynx and œsophagus, the stomach and duodenum, the small and the large intestine, with the mesenteric glands, and the solid abdominal viscera—namely, the liver, pancreas, and spleen. Affections of the two outlets of the alimentary canal—namely, the mouth, fauces, pharynx, and œsophagus, with the appended glands, and the rectum and anus—properly belong to the department of surgery, being either open to view or accessible by manual exploration, and often requiring surgical operations. These affections, for the most part, will not be considered in this work. This section will therefore be devoted mainly to the diseases affecting the hollow viscera and the solid organs within the abdomen. The affections of the digestive system, as of other anatomical systems, consist of—*first*, inflammation; *second*, structural lesions; and *third*, functional disorders. The diseases of the different divisions of the alimentary canal will be considered in their natural order, beginning with the affections of the upper part of this canal. The diseases of the mouth and of the tongue, such as the different varieties of stomatitis or of glossitis, belong to surgery. Certain affections of the mouth, prevailing especially in early life, are considered in treatises devoted to diseases of children.

Tonsillitis.

The most important varieties of tonsillitis are acute simple tonsillitis (often designated as catarrhal), follicular tonsillitis, and parenchymatous or suppurative tonsillitis, commonly known as quinsy. When the inflammation involves especially the lacunæ or crypts of the tonsils, the disease is called lacunar or follicular tonsillitis. Pseudo-membranous tonsillitis is usually present in true croup and in diphtheria, and is considered in connection with these diseases.

Acute Simple Tonsillitis is characterized, anatomically, by redness with moderate swelling of the tonsils and an inflammatory exudation from the mucous membrane, composed of mucus mingled with epithelial cells, pus-cells, and serum. This simple tonsillitis is present in most cases of acute pharyngitis, or ordinary sore throat. The tonsillitis contributes its share to the constitutional disturbance, pain, and other symptoms which will be described under

Acute Pharyngitis; but the affection of the tonsils is not usually so severe as to require a separate consideration.

Acute Follicular or Lacunar Tonsillitis is of considerable clinical importance. In this affection the inflammation involves not only the mucous membrane covering the surface of the gland, but especially that lining the crypts. The tonsils present little white patches composed of epithelial cells, pus-cells, mucus, and a large number of bacteria. These white deposits extend into the lacunar depressions. It is important to distinguish these white patches from a diphtheritic exudation with which they are sometimes confounded. In distinction from the latter the white masses in follicular tonsillitis form a pultaceous deposit, not a membraniform layer like the deposit of fibrin; they cannot be removed in strips like the latter; they are more easily removed, are more prominent, are more abruptly defined, and disappear spontaneously more quickly, than patches of fibrin. On close inspection the secretion will be seen to dip into the follicular depressions. The follicular deposit occurs without any abrasion of the mucous surface, but it is common for patients to consider the patches as ulcers.

Acute follicular tonsillitis is often attended by severe constitutional disturbance. The symptoms at the onset may be as severe as in diphtheria. Chilly sensations, or even a chill, may mark the beginning of the affection. The temperature rapidly rises, and within twenty-four or forty-eight hours may reach 104° or 105° . There are often headache, anorexia, insomnia, and other symptoms which usually attend marked pyrexia. The patient complains of dryness and soreness of the throat, and there may be considerable pain on swallowing. Usually within three to five days the fever and other symptoms subside and recovery is rapid. During, and sometimes for a considerable time after, the attack there may be marked prostration.

The prognosis is always favorable. The severity of the constitutional symptoms in many cases, together with the anatomical appearances, has often led to the diagnosis of diphtheria from which, as already stated, it is important that follicular tonsillitis should be carefully discriminated.

Parenchymatous Tonsillitis, or inflammation of the substance of the tonsil, may terminate in resolution, but usually it goes on to suppuration, constituting the disease called *suppurative tonsillitis* or *quinsy*. The tonsil of one side only or both tonsils may be affected. The tonsil becomes much enlarged and the seat of an abscess. The abscess may open at one or at several points on the surface of the tonsil. The inflammation usually extends to surrounding parts, the soft palate and uvula especially becoming hyperæmic and much swollen. The submaxillary gland is not infrequently enlarged.

Suppurative tonsillitis may attack a previously healthy tonsil, but it is particularly liable to occur in those whose tonsils are affected by chronic inflammation. The causation involves a predisposition to the affection, and persons predisposed are likely to experience repeated attacks. The immediate cause of the suppuration doubtless is to be found in micro-organisms which invade the substance of the tonsil.

Suppurative tonsillitis is a very distressing affection, in consequence of the pain and difficulty in deglutition. There is elevation of temperature, which may be considerable. Increased frequency of pulse, loss of appetite, headache, sleeplessness, pain in the limbs, are other symptoms which mark the febrile disturbance. Pain is a prominent symptom, this being most marked upon attempting to swallow. Sometimes pain is referred to the ear. The throat is at first dry; and subsequently there is a secretion of viscid mucus and of saliva, often in abundance. The voice is husky, and articulation may be difficult or almost impossible. Difficulty of breathing occurs when both tonsils are greatly swollen. A rare complication is œdema of the glottis, which

may cause death. The symptoms increase in severity until the abscess bursts or is opened, and then there is a notable and usually rapid abatement of the local and constitutional disturbances. A very exceptional occurrence is suffocation produced by escape of the pus into the larynx when the abscess ruptures during sleep. Fatal hemorrhage has been known to take place from ulceration of the abscess into the internal carotid or internal maxillary artery. These unfortunate terminations, however, are very rare, and the prognosis is to be considered as favorable.

It is not rare for little yellowish-white concretions to form in the crypts of the tonsils. These concretions consist of desiccated epithelial and pus-cells and low vegetable organisms. When crushed, these whitish pellets emit a very offensive odor. These concretions, which may contain lime salts, are sometimes mistaken for tubercles.

In acute simple tonsillitis the measures of *treatment* are those which will be mentioned in connection with Simple Pharyngitis.

In the follicular variety a solution of alum, borax, or the chlorate of potassa may be used as a topical application by means of a camel's-hair pencil brush. Gargles do not bring the solution in contact with the affected parts. In cases with marked pyrexia the tincture of aconite in small, frequently repeated doses should be given, until an impression is made on the pulse.

The treatment of parenchymatous tonsillitis, or quinsy, consists of poultices or the water-dressing to the neck, the inhalation of warm vapor, and anodynes to lessen discomfort. Milk is the form of nourishment best taken. When fluctuation is perceived, the abscesses may be opened and the patient will be relieved sooner than if they had been left to break.

Pharyngitis.

A variety of forms of pharyngitis are distinguished, many of which can receive only passing mention within the limits of this work.

In *Acute Simple Pharyngitis* the mucous membrane is congested, swollen, and coated with more or less of a muco-purulent secretion. The inflammation usually extends to the tonsils and soft palate, and it may also involve the nasal passages. This variety of pharyngitis is one of the forms of "a cold" or ordinary sore throat. There is usually more or less pain, especially in the act of swallowing. There is at first a sensation of dryness. The secretion of mucus at a later stage provokes efforts at hawking and expuition. If the inflammation extend low in the pharynx, coughing is excited. The cough is of a peculiar character, easily recognized and distinguished as a throat-cough, the forcible current of expired air being brought to bear on the pharynx. The limitation of the inflammation to the pharynx or its non-extension into the larynx is shown by the absence of huskiness or hoarseness of the voice. Febrile disturbance, except sometimes in children, is slight. The extent and intensity of the inflammation are to be ascertained by inspection of the throat. The involvement of the vault of the pharynx, the posterior nares, and the posterior surface of the palate and the lower part of the pharynx can be ascertained by the use of the laryngoscope and of the rhinoscope.

Acute simple pharyngitis sometimes occurs as an *epidemic* affection, in which case the disease is to be regarded as a form of fever rather than simply as a local inflammation. I have analyzed a series of twenty-three cases which occurred during such an epidemic in the western part of New York State in 1857.¹ From this analysis the conclusion was reached that the disease was an epidemic fever characterized by mild erythematic inflammation of the pharynx and fauces as the only constant local complication. The febrile

¹ *Buffalo Medical Journal*, vol. xii. p. 718.

movement was in a marked degree out of proportion to the local affection. Its duration was from three to five days. The epidemic prevailed extensively for about two months, both sexes and different ages being affected without notable discrimination. No proof of contagion existed. The affection was not scarlatina, but it resembled influenza, save that the pharyngeal and not the bronchial mucous membrane was the seat of inflammation. It is perhaps proper to regard the epidemic disease as a form of influenza.

Acute pharyngitis is a common complication in many acute infectious diseases, especially in the exanthematous fevers. Reference will be made hereafter to *Exanthematous Pharyngitis* in connection with scarlatina, measles, and smallpox.

The pharyngitis is designated as *erysipelatos* when it complicates erysipelas, particularly facial erysipelas. Usually, the inflammation is of the acute simple variety, but it may be gangrenous or suppurative, and in the latter case the prognosis is grave. It is claimed that erysipelas may attack the pharynx primarily.

Gangrenous Pharyngitis may occur also in connection with diphtheria, and rarely as a complication of scarlet fever, smallpox, typhoid fever, or other acute infectious disease. The symptoms assume a typhoid character and the termination is usually fatal.

In *Phlegmonous Pharyngitis* there is an accumulation of pus in the sub-mucous and deeper tissues of the pharynx, constituting a *retro-pharyngeal abscess*. This affection may occur traumatically, as by the penetration of a sharp piece of bone. More frequently it is secondary to caries of the cervical vertebræ.

Pseudo-membranous or *Fibrinous Pharyngitis* constitutes a part of the lesions in croup and in diphtheria, with which diseases it is considered.

Subacute Simple Pharyngitis is a very common affection, and is generally treated without the advice of a physician. The lesions and symptoms are similar to those in acute simple pharyngitis, but they are less intense.

Chronic Pharyngitis is an extremely common affection in this country. It is commonly known as "the catarrh." It may follow repeated attacks of acute pharyngitis, but it is generally a subacute affection at the beginning, and is developed imperceptibly. It is customary to distinguish two forms of chronic pharyngitis—namely, simple chronic pharyngitis, and chronic follicular or granular pharyngitis. In *simple chronic pharyngitis* the mucous membrane is inflamed without especial involvement of the lymphatic follicles of the pharynx. The membrane is more or less reddened and thickened. Frequently small, dilated veins can be seen mapping out irregularly the surface of the pharynx. Viscid mucus adheres to the surface of the inflamed mucous membrane. In *follicular* or *granular pharyngitis* the follicles of the pharynx are enlarged in consequence of hyperplasia of their lymphoid cells. These enlarged follicles form little nodules studding the surface of the pharynx. They are surrounded by congested and inflamed mucous membrane. In both forms of pharyngitis—between which, in fact, no sharp line of distinction can be drawn—the inflammation may extend to adjacent mucous membranes. When the inflammation extends to the Eustachian tubes or their openings, deafness is produced in greater or less degree. When chronic pharyngitis has existed for a long time, portions of the mucous membrane are likely to become atrophied.

Chronic pharyngitis in some persons occasions but little inconvenience. It is often found when the patient makes no complaint of any trouble in the throat. In other cases it occasions more or less annoyance. An uncomfortable sensation is felt in the throat. The presence of adhesive mucus excites efforts of hawking and coughing. The proximity of the inflammation to the

larynx may give rise to a dry, hacking cough. The voice becomes hoarse after considerable use in speaking or reading, and the use of the voice is followed by a sense of fatigue in the vocal organs.

The affection is much more frequent in men than in women. It occurs most frequently after puberty and in middle life. The form of the disease which is sometimes called *clergyman's sore throat* is usually of the follicular variety. This form of the disease occurs in those who are under the necessity of using the voice a great deal in public speaking, but it is probable that in these cases the excessive use of the voice is not the only cause, for chronic pharyngitis in general occurs most frequently in persons of sedentary habits who suffer from the wear and tear of continued application without physical and mental relaxation. The number of persons is very large in this country who overtask the powers of the system by steady labor in the office, the counting-house, or the workshop, continued without intermission for many years. It is especially among those who in this way violate the laws of health that chronic pharyngitis prevails. It seldom occurs among the so-called laboring-classes, and it is much more frequent in cities than in the country. Occurring in persons of sedentary habits, it is usually accompanied by symptoms denoting impairment of the general health. The patients complain of debility and a want of their accustomed energy; they are generally depressed in spirits; and they often fancy the existence of some serious disease, especially pulmonary consumption. Dyspeptic ailments frequently coexist.

The diagnosis of chronic pharyngitis is readily established by inspection of the throat. The use of the pharyngeal mirror is of service in determining the extent of the lesion.

The prognosis of chronic pharyngitis is favorable so far as life is concerned, but it is not favorable as regards the return of the mucous membrane to its healthy state. The tendency of the disease is to long continuance. There is no tendency of chronic pharyngitis to eventuate in laryngitis or bronchitis, nor is there any tendency to the development of tuberculosis.

The annoyance from chronic pharyngitis is often much enhanced by patients concentrating their attention upon it. They sometimes fall into the habit of constant hemming or "clearing the throat," which is not only fatiguing to themselves, but extremely disagreeable to others.

Tuberculous Pharyngitis is characterized by the growth of tubercles and the formation of tuberculous ulcers in the pharyngeal mucous membrane. Although simple pharyngitis is not uncommon in chronic pulmonary tuberculosis, a genuine tuberculous pharyngitis is infrequent. Sometimes tubercles can be seen during life in the floor or sides or neighborhood of the ulcers; but at other times there is nothing distinctive in the gross appearance of the ulcers, although microscopically their tuberculous nature is evident. Tuberculous ulcers form most frequently at the sides of the larynx and on the palatine folds; and from these situations they may extend to the soft palate and to the posterior wall of the pharynx. Portions of the mucous membrane, particularly that of the uvula, often become irregularly thickened and of a grayish color. In tuberculous pharyngitis there is usually marked pain upon deglutition. The lymphatic glands of the neck are usually swollen.

The diagnosis is to be based upon the recognition of tuberculous disease elsewhere, particularly in the lungs, and by the detection of tubercle bacilli in the secretion from the ulcers.

Tuberculous pharyngitis sometimes runs an acute course, and at other times it is chronic.

Syphilitic Pharyngitis may occur during any stage of syphilis, either congenital or acquired. The manifestations of syphilis begin more frequently upon the tonsils and palate than upon the pharynx. Initial syphilitic sores

have been seen upon the tonsils, the palate, the pharynx, and the epiglottis. An erythematic inflammation of the tonsils and palate, extending to the pharynx, is among the earliest and most frequent manifestations of secondary syphilis. The inflamed regions are usually symmetrically situated. Mucous patches are common. These are due to thickening and opacity of patches of epithelium, together with infiltration of the subjacent tissue with lymphoid cells. A secretion, sometimes purulent, takes place from these patches. The mucous patches are usually of short duration, especially under appropriate treatment. Syphilitic ulcers may form in the secondary, but they are most common in the tertiary, stage of syphilis. Tertiary ulcers may be due to the softening and destruction of gummata, or they may result from suppuration. Syphilitic ulcers occur most frequently on the soft palate and palatine folds, but they may extend to the pharynx or may involve the latter primarily. These ulcers are irregular in shape, with undermined edges and surrounded by a zone of congestion. A sequel of syphilitic ulceration is the formation of cicatrices, the recognition of which may aid in the diagnosis of pre-existing syphilis. In rare instances these cicatrices by their extent and contraction occasion serious distortions and stenoses of the pharynx.

The symptoms of syphilitic pharyngitis do not differ materially from those of simple and ulcerative pharyngitis due to other causes, except that pain is rarely a marked symptom, and frequently there is little or no increased sensibility of the throat.

The diagnosis is made by means of a syphilitic history, by the appearances of the inflammation and ulceration already described, and especially by the readiness with which the lesions usually respond to antisyphilitic treatment.

The prognosis is good. Destructive ulcerations with extensive involvement of the bones are much less frequent now than in former times.

Thrush, a disease belonging more appropriately to the affections of the mouth, will receive only brief consideration here. Thrush is characterized anatomically by the appearance of white or brownish-white, curdy patches upon the affected mucous membrane. These patches are composed essentially of the mycelium and spores of a fungus which is usually called *Oidium albicans*, but the exact systematic classification of the fungus has not been determined. The mucous membrane beneath these parasitic patches is usually congested, but not ulcerated.

Thrush is observed most frequently in the mouth and on the palate, but it may involve the pharynx, and it is not infrequent in the œsophagus. It has even been seen in the stomach.

Thrush is a symptomatic affection. It occurs most commonly in nursing infants, especially in those fed by bottle in hospitals and asylums where sufficient attention is not given to cleanliness of the mouth and of the nursing-bottle. Thrush, may, however, occur in adults, and is then observed in conditions of great prostration of the vital forces, as in old people, and toward the termination of such exhausting diseases as carcinoma, tuberculosis, diabetes, dysentery, and typhoid fever.

As regards the TREATMENT of thrush, the borate of sodium is an efficient remedy. This remedy is best applied dissolved in glycerin. Applications by means of a camel's-hair pencil brush may be made three or four times daily. In addition to these applications the indications for treatment are to be derived from the pathological conditions with which this local affection is associated.

Acute simple pharyngitis, occurring as a sporadic disease or as the anatomical characteristic of an epidemic fever, is usually a mild affection, having no tendency to end fatally. (Edema of the glottis is an accident which may occur, but it is extremely infrequent. I have met with one example of its occurrence in a case of sporadic pharyngitis. The therapeutical measures

indicated are mild purgatives, followed by anodyne remedies, quinine, and the chlorate of potassa. Gargles of the chlorate or the nitrate of potassa are usually prescribed, but the liquid can in this way be brought into contact with the inflamed membrane to only a limited extent. A mucilaginous liquid or glycerin taken in small quantity and swallowed will allay the dryness and irritation of the throat. Small pieces of gum allowed to dissolve in the mouth have the same effect. The chlorate of potassa, taken in the form of troches, is more efficient than in solution and used as a gargle. Caustic or stimulating applications to the inflamed membrane are not called for. A sinapism externally, liniments containing chloroform, aconite, and laudanum, and the water-dressing give relief.

The treatment of chronic pharyngitis, to be effective, must have reference to the system. Topical applications alone are rarely efficacious. A fair trial of them, however, should be made. The nitrate of silver in strong solution (20 or 30 grs. to the ounce) in some cases, especially those of the granular variety, is highly useful. [In this variety the best results are obtained by separate cauterization of each granule or follicle. For this purpose nitrate of silver, chromic acid, sulphate of copper, or, best of all, the galvano-cautery, may be employed. The application of the latter is attended with little or no pain, but the inflammation which it excites is more destructive to the granulations than that caused by chemical substances. After using the cautery the patient should be directed to suck pieces of ice in order to keep the inflammatory reaction within moderate bounds. The galvano-cautery is also most effective in reducing the bulk of hypertrophied tonsils. For this purpose the application is a momentary one, and should not be repeated more than once a week.—H.] Local applications are made by means of a probang, mop, or large camel's-hair pencil brush. A solution of tannin is often of service. The chloride, iodide, or sulphite of zinc and iodoform are recommended. Inhalations are not appropriate; they carry the medicated application too far. On the other hand, gargles are of little use; they do not carry the application far enough. Projecting a spray of medicated solution into the throat is an efficient mode. Applications to the posterior nares may be made by means of the nasal douche; if made by injecting from the fauces, there is danger of the fluid passing into the Eustachian tubes and causing otitis media. The constitutional remedies which exert a curative influence in certain cases are the iodide of potassium, the bromides, the chlorate of potassa, and the hydrochlorate of ammonia. Alteration of the habits of life is first in importance. Relaxation, recreation, and out-of-door life are far more efficacious than medicines, and the latter are of little use without the former. When circumstances permit, relinquishment of business for a time for travel or rural occupations is of signal benefit. Tonic remedies may often be advantageously conjoined with proper hygienic management. Tonics, to be efficacious, should be continued for a long period, and the form of tonic changed from time to time. The diet should be nutritious. The object of treatment, in short, is to restore the general health.

For syphilitic pharyngitis local and general antisyphilitic measures of treatment are indicated. (For these the reader is referred to works which treat of syphilis.)

Diseases of the Œsophagus.

Inflammation of the œsophagus (œsophagitis), acute, subacute, or chronic, is extremely rare. As an idiopathic, non-traumatic affection it may be said almost never to occur. It may be produced by the ingestion of corrosive

poisons, by the irritation of foreign bodies, and by an extension of inflammation from adjacent parts. In some parts of this country, especially in the Southern States, inflammation and stricture are frequently caused by drinking accidentally a caustic preparation used for washing and scouring purposes known as "concentrated lye."¹ In cases of diphtheria the diphtheritic affection sometimes extends into the œsophagus, and ribbon-like pseudo-membranes may be expelled. The eruption of smallpox occasionally occurs in this situation.

The diagnostic symptoms of inflammation are pain and soreness localized in this situation, and especially manifest in acts of deglutition. The passage of an œsophageal sound occasions pain, and on its withdrawal mucus or pus may be adherent to it. The latter are evidence of œsophagitis only when carcinoma of the cardiac orifice of the stomach is excluded by the absence of obstruction.

The rational indications for treatment are the nourishment of the patient by a bland liquid diet, of which milk should be the basis, and, if this occasion pain, rectal alimentation may be substituted therefor.

Stenosis, caused by morbid growths, cicatrized ulcers, etc., is ascertained by exploration with the sound, in conjunction with the evidence of obstruction to the ingestion of food. Primary carcinoma occurs in the œsophagus. The consideration of these affections belongs to surgery. In this category belong foreign bodies, the presence of vegetable and animal parasites, dilatations, and diverticula. Rupture of the œsophagus is an occasional accident.²

Obstruction may depend on compression by an aneurism or a tumor of some kind. The obstructing cause in these cases is generally apparent. The fact of obstruction in a person over forty years of age should always suggest exploration for the signs of an aneurismal tumor. Rupture of aneurisms sometimes takes place into the œsophagus. Ulcers having the characteristics of gastric ulcer may occur in the lower end of the œsophagus.³

Perforation from the presence of a foreign body may establish a communication with the pericardial or the pleural cavity, and it may cause subcutaneous emphysema of the neck and the escape of swallowed fluids into the areolar tissue. Cases have been reported of softening and perforation of the lower portion of the œsophagus by the gastric juice.

Paralysis of the muscular coat, in connection with that of the pharyngeal muscles, may occur after diphtheria, in connection with bulbar paralysis, and in some cases of general paralysis and of cerebro-spinal multiple sclerosis.

Spasm of the œsophagus (œsophagismus) of transient duration is one of the hysterical manifestations. Irrespective of that connection it may cause obstruction for hours and days. In a case reported by Dr. J. J. Henna, which I saw in consultation, complete obstruction from spasm had existed for eight days, and was instantly and permanently removed by a single introduction of a sound.⁴

(For a full account of the diseases of the œsophagus the reader is referred to Cohen's treatise on the *Diseases of the Throat*, and to his articles in *Peper's System of Medicine, by American Authors*, vol. ii.)

Parotiditis—Mumps.

The affection commonly known as mumps may be appropriately noticed in this connection as seated in an organ accessory to the buccal cavity. The disease is infectious and contagious. It therefore involves a special cause which, reasoning from analogy, is a parasitic organism. The existence of this *contagium vivum* has not as yet been demonstrated. Mumps often prevail as an epidemic. The most marked local affection in this disease is inflammatory swelling of the parotid gland and surrounding connective tissue. As the disease rarely terminates fatally, little is positively known of the anatomical changes in the gland. The interstitial tissue of the gland is believed to be infiltrated with serum and to contain a few emigrant white blood-corpuscles. The epithelium of the acini and ducts of the gland may be supposed to swell up and undergo parenchymatous degeneration. An inflammatory œdema of the connective tissue about the gland exists in most cases. More serious structural changes than those described are not supposed to exist, as the restitution of the gland and of the surrounding tissues to their normal condition occurs with such ease and rapidity. Virchow teaches that the inflammation has its point of departure in the ducts, and is propagated from simple inflammation of the buccal mucous membrane (stomatitis). According to this view, the infectious agent gains access to the gland from the mouth by Steno's duct. A similar coincident inflammation of the submaxillary and sublingual glands is not infrequent. Cases have been described in which these glands were involved and the parotid escaped. Erythematous inflammation of the mouth and pharynx is frequently present in cases of epidemic parotiditis.

The period of incubation varies from ten to eighteen days. The disease is frequently ushered in by a slight chill or by chilly sensations, and in its progress it may be accompanied with moderate febrile movement, diminished appetite, pain in the head, and general malaise. A certain degree of febrile disturbance usually precedes for a short time the enlargement of the parotid gland, and generally subsides before the swelling fully disappears. The swelling usually begins in one gland, but with few exceptions both glands become involved, although the one first affected suffers more. The amount of swelling in the site of the parotid gland varies in different cases. If considerable or great, it causes a notable change in the physiognomy. The skin generally is not discolored, but there may be an inflammatory blush. The mucous membranes of the mouth, pharynx, and conjunctiva are often moderately inflamed. Pain upon moving the jaws and difficulty in swallowing are experienced. The disease continues for from four or five days to two weeks. The swelling, pain, and soreness gradually subside and disappear. The inflammation has no tendency to suppuration or to continue in a chronic form. An abundant perspiration sometimes takes place at the time of convalescence.

In males, after the age of puberty, one, rarely both, of the testicles may become inflamed. This orchitis is usually called metastatic. When it appears the swelling in the parotid sometimes subsides. This so-called metastatic orchitis is not very frequent. It seems to be more frequent in some epidemics than in others. Most of the statistics bearing on its frequency have been derived from military practice. The largest compilation from this source has been made by Granier.¹ In 495 cases of parotiditis

¹ *Lyon méd.*, No. 26, 1879.

In Laveran's collection of 432 cases in soldiers, orchitis occurred 156 times. In 32 cases of orchitis observed by Laurens (out of 118 of parotiditis), one testicle alone was affected in 26 cases, and both testicles in 6 cases. In 16 of these cases Laurens observed distinct atrophy within two months.

soldiers, orchitis occurred in 115; that is, in 24 per cent. of the cases. Atrophy of the affected testicle often follows this inflammation. According to Granier, atrophy occurs in 44 per cent. of the cases of orchitis, and in 10½ per cent. of the cases of parotiditis. The shorter the duration of the orchitis, the less probability is there of atrophy of the testicle. In females a similar inflammatory swelling of the mammary gland and of the ovary has been observed as an exceptional occurrence. When parts other than the parotid are involved, this is not, strictly speaking, from a metastasis, but from the operation of the same internal morbid condition which occasions the inflammation of the parotid.

In very rare instances epidemic parotiditis is of an unusually severe character. The fever and constitutional disturbance may be exceptionally high. Maniacal delirium and other severe cerebral symptoms have been observed. The patient has been known to sink into a typhoid state. Convulsions sometimes occur in children; but facial spasm is less infrequent. The gland has been known to suppurate in this disease. These occurrences, however, are so rare as to be regarded more as curiosities than of practical importance.

The communicability of this disease is generally admitted, but it has been denied by some writers of high authority; for example, by Valleix. Persons between twenty and thirty years of age are most susceptible to the contagium, but it occurs not infrequently under puberty. Males are more susceptible than females. It is one of the diseases which affect the same person but once.

The prognosis is generally favorable, the complications and accidents which have been mentioned being exceptional. Except that it occasions considerable discomfort, the disease in most cases is trivial. In the way of treatment it claims only soothing embrocations and the application of flannel, cotton batting, or wool to the neck, with some anodyne remedy if the pain be considerable. Bloodletting, purgation, or other of the so-called antiphlogistic measures are not indicated. [The infusion of jaborandi is recommended on the ground that it is excreted by the salivary glands, the function of which it increases, and so hastens the elimination of the micro-organisms which are believed to be the cause of the disease.—H.] The popular apprehension of danger from "taking cold" in this disease is based on the idea that if the affection of the parotid be arrested a metastasis is likely to take place. There is little ground for this idea, but a patient probably passes through the disease more comfortably by avoiding exertion and exposure.

Parotiditis occurs as an occasional complication of typhus and typhoid fever, pyæmia, and pneumonic fever. Under these circumstances it is a widely different affection from mumps. Suppuration takes place in the great majority of cases, the abscesses evacuating either externally or into the meatus auditorius, and frequently there is considerable sloughing of the areolar tissue. As a complication of fever it is attended with much suffering and danger.

Acute suppurative inflammation of the connective tissue around the submaxillary gland is called by German writers *angina Ludovici*. There is present in the suprahyoid region diffuse cellulitis, combined often with gangrene and sloughing of the tissues. The inflammation may extend to surrounding parts. The affection is a grave one. The most favorable termination is in abscess. Death occurs from œdema glottidis, secondary pneumonia, or septicæmia. The treatment is mainly surgical.

CHAPTER II.

INFLAMMATORY DISEASES OF THE STOMACH AND OF THE DUODENUM.

Acute Gastritis.—Subacute Gastritis.—Chronic Gastritis.—Phlegmonous Gastritis.—Chronic Interstitial Gastritis.—Gastro-duodenitis.—Duodenitis.

Acute Gastritis.

THE term acute has been applied to inflammation of the stomach by different authors with a widely different scope of signification. In the cases of gastritis to which heretofore, by many authors, the term acute has been restricted, the disease is attended with extreme danger to life, ending fatally as a rule. In these cases almost invariably the disease is caused by toxic agents—namely, the corrosive or acrid poisons. Acute gastritis was considered as thus restricted in the previous editions of this work. On the other hand, some authors include under the name acute gastritis or acute gastric catarrh gastric inflammation of every grade of intensity, and also certain affections generally regarded as functional. It is in accordance with the application of the term acute to other diseases to extend its scope, as applied to gastritis, so as to embrace all cases in which the inflammation has considerable severity, obliging patients generally to keep the bed. Acute gastritis will be considered in this sense in the present edition of this work. Cases in which the intensity of the inflammation is not sufficient to entitle it to be called an acute disease will be included under the heading Subacute Gastritis. Cases of chronic gastritis are those in which subacute inflammation is more or less persistent.

Adopting the more comprehensive scope of the term acute gastritis, the disease, exclusive of toxic cases, is not of very frequent occurrence—a fact which would not *a priori* be supposed, considering the quantity of ingesta received into the stomach daily, the various stimulating and irritating substances which often enter into these, the great functional activity of the organ, the amount of blood which it claims during digestion, and the extensive glandular apparatus which it contains.

ANATOMICAL CHARACTERS.—More knowledge and caution are requisite in determining the existence of inflammation of the stomach than of any other organ. The stomach often presents after death various appearances simulating disease, but which are independent of any morbid process. These deceptive appearances are dependent chiefly upon two factors—namely, the varying amount of blood in the organ within physiological limits, and the rapid post-mortem softening of the mucous membrane in consequence chiefly of self-digestion. These changes, which are most intense in the fundus of the stomach, will be mentioned subsequently under the head of Softening of the Stomach.

It is very difficult to discriminate the milder grades of gastric inflammation from post-mortem changes. Hence, the observations of Beaumont upon Alexis St. Martin, who had a fistulous opening into his stomach, are of special value, and are usually cited as descriptive of the mild forms of acute inflammation of the stomach. These morbid appearances were noticed after indiscretion in eating or following the abuse of ardent spirits, and were accompanied with corresponding local and constitutional symptoms. They rapidly disappeared under proper medication and attention to diet. Beau-

most noticed during these attacks of mild gastric inflammation a livid, erythematous redness distributed in irregular, small patches. Sometimes the mucous membrane was pale. Ecchymoses and oozing of grumous blood from certain red spots of the gastric mucous membrane were also observed. The secretion of gastric juice was deficient, and was replaced by a considerable quantity of ropy, alkaline mucus which became yellowish or muco-purulent when the inflammation was unusually severe. Slightly elevated discolored spots, resembling deposits of false membrane and called aphthous by Beaumont, were also described.

In cases of more severe gastritis the mucous membrane usually presents irregularly scattered spots of congestion. Occasionally the redness is more diffused, and it may happen that the inner surface of the stomach presents a pale rather than a congested appearance. Ecchymoses, especially upon the summits of the gastric rugæ, may be present in large number. The mucous membrane is thickened, softened, and more opaque than normal. Its surface is coated with a thick layer of tenacious mucus or muco-pus. The swelling may extend to the submucous tissue. The changes are most marked usually in the pyloric portion of the stomach, and are more distinctive of inflammation when in this situation than when in the fundus. Hemorrhagic erosions, which consist of round or oval superficial abrasions of the mucous membrane upon a hemorrhagic base, are not infrequent.¹ Upon microscopical examination hyperæmia of the capillaries of the mucous membrane, particularly of those about the summits of the gastric tubules, and extravasations of blood, are detected. The intertubular tissue is thickened by the presence of serum and of extravasated red and white corpuscles. The accumulation of white corpuscles or pus-cells is most evident about the muscularis mucosæ. They may also be present in the submucous tissue. The epithelial cells of the gastric tubules may either remain unchanged or they may undergo cloudy swelling; that is, become enlarged by the accumulation of albuminous granules. In some cases this may be followed by fatty degeneration. Sometimes the tubules appear to be filled with a granular matter containing anæci, but without distinct cell-boundaries. This parenchymatous degeneration in the glands of the stomach often occurs in fevers, particularly in infectious diseases, and sometimes in phosphorus-poisoning, without evidence of inflammation, but with symptoms of disturbed digestion during life.² The cylindrical epithelial cells lining the inner surface of the stomach and the mouths of the gastric tubules become swollen with a secretion of mucus which escapes from their free ends. These cells are found in the mucus coating the mucous membrane, but to what extent they desquamate during life is a matter of uncertainty. The solitary follicles of the stomach (or lenticular glands, as they are also called), when present, are often swollen. They sometimes seem to be increased in number in inflammatory conditions of the stomach. Wilson Fox describes the development of follicular ulcers from these structures.

It is not intended to describe here the manifold morbid appearances belong-

¹ Brinton describes a special and severe form of gastritis characterized by the presence of a large number of hemorrhagic erosions. The contents of the stomach are stained with blood. He calls the affection hemorrhagic erosion of the stomach or ulcerative gastritis. Hemorrhagic erosions, however, are frequently found in the stomach under a great variety of conditions, and it is not probable that they possess much pathological significance.

² Virchow, in conformity with his views of inflammation, describes this parenchymatous change as inflammatory, and designates the process in this situation as glandular gastritis or gastradenitis; but Cornil and Ranvier justly remark that the inflammatory nature of this lesion is very doubtful. Elstein finds, in cases of poisoning by phosphorus or by alcohol, the parenchymatous degeneration most marked in the chief, or adelo-morphous cells of the gastric tubules (*Virchow's Archiv*, 1872, Bd. 55, S. 469).

ing to toxic gastritis; that is, gastritis produced by swallowing irritant poisons. These are in some cases characteristic of the action of special poisons, and are described in works on special pathological anatomy and on forensic medicine. The corrosive poisons, such as strong mineral acids and alkalis, cause necrosis and sloughing of the mucous membrane to a greater or less extent, and may produce such destruction of the coats of the stomach as to lead to perforation of its wall during life, with the escape of its contents into the peritoneal cavity. Some of these poisons cause the formation of a diphtheritic exudation in the gastric mucous membrane. They may be accompanied by characteristic changes in the color of the mucous membrane and of the contents of the stomach. When corrosive poisons are swallowed, more or less inflammation, and perhaps sphacelation, may be present in the mouth, pharynx, and œsophagus, but these signs are sometimes wanting. The inflammation in cases of acute gastritis may extend into the duodenum.

CLINICAL HISTORY.—Acute gastritis gives rise to pain more or less intense, referred to the epigastrium, together with a painful sense of constriction. The pressure of the diaphragm upon the stomach in inspiration sometimes increases the pain, so that the breathing may be costal and the number of respirations per minute is increased. Nausea and vomiting are prominent symptoms. In some cases the stomach is intolerant of water or the blandest liquids, even in very small quantities. The vomited matter is muco-serous, of a greenish color, the presence of bile being evident from the bitter taste, and not infrequently it is sanguinolent. The acts of vomiting occasion suffering. The thirst is frequently, but not always, intense. The desire for cold water is sometimes so irresistible that the patient is not deterred from drinking it by the painful acts of vomiting which it provokes. Tenderness on pressure over the epigastrium is often marked. The pulse is more or less frequent and small. The temperature of the skin is moderately, and sometimes considerably, raised. The thermometer, however, as a rule, shows but a moderate fever-heat, rarely exceeding 101° or 102° F. The bowels are constipated except in cases of poisoning. Dysphagia and aphonia are occasional symptoms. The tongue presents no special morbid appearances. The buccal fluids are diminished and frequently have an acid reaction. The patient suffers from cephalalgia. The mind is depressed and the expression is anxious and haggard. If life be not speedily destroyed and the disease run on to a fatal termination, vomiting of black, grumous, coffee-ground matter may occur, especially in cases of toxic gastritis. Toward the close of life the contents of the stomach are ejected by acts of regurgitation rather than by vomiting. The prostration in fatal cases becomes extreme. Hiccough occurs. The pulse becomes very frequent and thready. Coldness of the surface is marked. The mode of dying is by asthenia. If the disease end in recovery, improvement in all the symptoms takes place slowly; convalescence is gradual, and the inflammation may persist in a chronic form. In cases of gastritis produced by the corrosive poisons, if perforation of the stomach occur, the symptoms of peritonitis are added. Jaundice occurs in some cases, showing that the inflammation extends into the duodenum. The foregoing sketch of the symptomatology applies to cases of marked severity. In less severe cases the symptoms are essentially the same, but with less intensity.

PATHOLOGICAL CHARACTER.—The stomach, aside from its office as a receptacle of the ingesta, is a glandular organ, furnishing daily a large quantity of an important secretion—the gastric juice. In its reluctance, so to speak, to take on acute inflammation from the internal and inappreciable causes which give rise to the so-called spontaneous inflammations in other situations, it resembles other glands, such as the liver, pancreas, and kidneys.

When acute inflammation is developed in this situation it does not differ in pathological character from acute inflammation seated elsewhere in a mucous structure. The gravity of the disease depends on the physiological relations of the stomach. Acute gastritis produced traumatically, by the action of caustic or irritant poisons is developed like inflammation from the action of the same local causes in other situations.

CAUSATION.—Exclusive of the acrid or corrosive poisons, the most frequent cause in this country is spirit-drinking. I have known the disease to directly follow a debauch, and to prove rapidly fatal. A person with chronic gastritis induced and kept up by habitual spirit-drinking is liable to the acute affection after an unusually excessive indulgence. Exposure to cold may act as an auxiliary cause. In a case under my observation, the patient being an habitual drinker, the disease followed sleeping in a cold cellar. Over-repletion of the stomach with stimulating and indigestible food may sometimes give rise to acute gastritis. This so-called *crapulous gastritis* is generally subacute. It is a traditional error to consider as exciting causes drinking cold water when the body is perspiring, intense mental emotions, and contusions of the abdomen.

DIAGNOSIS.—The symptoms of acute gastritis are strongly diagnostic. There is greater probability of the disease being incorrectly supposed to exist than of its being mistaken, when existing, for other diseases. Vomiting, however frequent and persistent, is never alone sufficient evidence of gastritis. I have known a case of chronic meningitis with persistent vomiting to be treated for acute gastritis, the error not being discovered prior to the autopsy. Peritonitis, if accompanied with vomiting, may assume an appearance of gastritis, but the diffusion of tenderness over the abdomen, the tympanitic distension, and the rigidity of the abdominal muscles generally suffice for this differential diagnosis. Gastritis has been mistaken for pneumonitis, but physical exploration of the chest should enable the physician to detect or exclude the latter affection.

Gastralgia was formerly confounded with gastritis. The paroxysmal recurrence of pain or its occurrence in marked exacerbations, the absence of febrile movement, of vomiting, as a rule, and of tenderness on pressure, and the ability to take food, sometimes with relief of the pain, sufficiently characterize the affection as neuralgic.

With a view to appropriate antidotal treatment, and also in a medico-legal point of view in certain cases, it is desirable to determine from the symptoms whether acute gastritis be attributable to poison. This is always to be suspected in severe cases if other causes be not evident. Burning in the throat is complained of if a caustic or corrosive poison have been taken, and the local action of the poison may be seen in the mouth and fauces. The matters vomited are likely to contain blood. Diarrhœa is likely to occur. If caused by a poison the disease is developed suddenly, and inquiry is to be made to ascertain if the sudden development were not immediately preceded by a meal or the ingestion of something in the way of food or drink.

PROGNOSIS.—Cases of acute gastritis, in the restricted sense in which the term acute was formerly used, were, in the great majority of cases, fatal. In the more comprehensive scope of the term the disease ends in recovery, as a rule, if toxic cases be excluded. Death sometimes takes place within a few hours, patients falling quickly into a condition of collapse. These cases, however, are exceptional. The mode of dying is by slow asthenia.

When the disease is due to the action of a corrosive poison the danger will depend, other things being equal, on the amount of local injury.

TREATMENT.—The indications for bloodletting are not present in this disease. Bearing in mind that the danger is from asthenia and that life is sometimes quickly destroyed, the abstraction of blood is not admissible. The first and most important object in the treatment is to secure for the inflamed organ absolute rest. With reference to this object the less of anything introduced into the organ the better. To allay intense thirst small pieces of ice may be swallowed, or iced water taken often in a very small quantity at a time. The physician should resist the temptation to try in succession the host of remedies to allay vomiting, all of which will be likely to aggravate this distressing symptom. It is desirable to administer opiates in order to quiet the stomach and render the system more tolerant of the disease. A salt of morphia placed dry upon the tongue may be tried, and if vomiting be provoked by this mode of administration it should be administered hypodermically or some form of opiate given per enema. Fomentations or a blister may be applied over the epigastrium. Cathartics are inadmissible. The bowels may be moved by stimulating enemas. Mercury, either in large or small doses, is not indicated. The importunities of the patient for an emetic are to be resisted. There may be a feeling as if the stomach were distended or as if there was an accumulation aggravating the distress. This feeling arises from the inflamed state of the membrane, as tenesmus is incident to inflammation of the rectum, and it may be called gastric tenesmus.

Alimentation is not less important than in other diseases, and in proportion as the symptoms denote danger in the direction of asthenia supporting measures of treatment are indicated. The stomach will not tolerate alcoholics and food; moreover, their introduction into the stomach conflicts with the most important object of treatment—namely, absolute rest of the inflamed organ. The rectum is to be substituted for the stomach as regards the reception of ingesta. This is a disease in which rectal alimentation is of invaluable service. Alimentary support may be adequately provided thereby during a period as long as may be required; that is, until the acute symptoms have subsided and the stomach will tolerate bland nourishment. From three to four ounces of defibrinated blood, Leube's pancreatic meat emulsion or his "meat solution," or milk with the addition of egg (the election of any of these articles being made after experimental trials, and perhaps the different articles employed in alternation), may be injected every four or six hours. If alcoholic support be indicated, spirit may be added to the rectal food according to the urgency of the indication, or the latter may be administered hypodermically. The addition of a little laudanum to each injection is generally advisable. Thirst may be relieved by the injection of water from time to time and frequent sponging of the body. The danger from the disease is much lessened and the duration shortened by pursuing this course.¹

Milk with the addition of lime-water will be likely at first to be best borne by the stomach, given in small quantities at short intervals. Other

¹ The pancreatic meat emulsion is prepared as follows: To 5 ounces of finely scraped meat add 1½ ounces of finely chopped pancreas and 3 ounces of warm water. The mixture should have the consistence of thick soup. Leube's meat solution is prepared by adding hydrochloric acid with water, and employing heat by means of a Pepin's digester. (Vide "Ueber die Therapie der Magenkrankheiten," von W. O. Leube, *Sammlung klinischer Vorträge von Volkmann*, No 62, Leipzig, 1873.) The bowels should be thoroughly washed out by a large enema both before beginning rectal alimentation and afterward from time to time. Laudanum added to the injections promotes their retention, and probably their absorption.

Of food are to be gradually added. After the inflammation has ceased the stomach is left in an atonic condition, and remedies of a tonic character are indicated during convalescence. If the acute end in the chronic form of inflammation, the treatment due to chronic gastritis is to be employed.

Acute gastritis caused by the acrid or corrosive poisons is to be treated after the plan just stated, with the addition of measures having reference to the evacuation and neutralization of the poisonous substance. Emetics are to be promptly given, and if they fail to act efficiently the stomach-pump is to be resorted to, provided the poison be one which can be ejected. Arsenic, corrosive sublimate, alcohol, antimony, cantharides, copper, phosphorus, together with a great number of vegetable irritants, such as capsicum, gamboge, croton oil, etc., may be expelled from the stomach; but if any of the corrosive acids have been taken, reliance must be placed on the prompt administration of antidotes. Antidotes are also to be given after the employment of emetics or the stomach-pump to effect the removal of acrid poisons. (For details respecting the management of cases of poisoning the reader is referred to works which treat of toxicology.¹) I shall simply subjoin, for the convenience of the practitioner, an enumeration of the antidotes for the more important of the poisons which act locally upon the stomach.

Arsenical Preparations: The hydrated sesquioxide of iron is the special antidote. It should be recently prepared and given in large quantity. If this preparation be not immediately available, the sesquioxide or common red oxide of iron (crocus martis) may be given in its stead. Bouchardat advises to combine magnesia with the preparation of iron, in order to promote the passage of the iron from the stomach into the intestines.

Corrosive Sublimate and other Salts of Mercury: The most reliable antidote is albumen, and the white of eggs is the best and most available article.

Salts of Copper: Albumen is an antidote. Iron reduced by hydrogen and the hydrated persulphate of iron are said by Bouchardat to be antidotal both to the salts of mercury and of copper.

Tartar Emetic: Substances containing tannin in abundance and magnesia.

Nitrate of Silver: Chloride of sodium.

Mineral Acids: Magnesia or chalk mixed with water or milk; the alkaline carbonates or soap.

Oxalic Acid: Magnesia, chalk. Whiting or plaster scraped from the wall of an apartment may be given, mixed with water. Alkalies are not to be given.

Ammonia: Vinegar or any of the vegetable acids.

Potassa and Soda: The same.

Subacute Gastritis.

Subacute gastritis, not becoming chronic, but of transient duration, occurs not infrequently. It is not easy to say with positiveness how frequently it occurs, because practically it is difficult to draw the line of demarcation between slight inflammation and merely functional disturbance in this situation. Subacute gastritis doubtless enters into certain cases of the affection which will be noticed in connection with functional disorder of the stomach under the name of Acute Dyspepsia. Subacute inflammation of the stomach is much more frequent in infants and young children than in the after periods of life. As here considered, reference will be had chiefly to the affection occurring at a time subsequent to the period of infancy.

¹ *Taylor on Poisons* may be consulted for this purpose; also, article "Poisons" in *Dowling's Medical Dictionary*.

The degree of inflammation in different cases of subacute gastritis varies, being either slight or moderate as evidenced by the local and general symptoms. The local and general symptoms are marked according to the degree of the inflammation. The ingestion of food is followed by uneasiness or distress referred to the epigastrium, and by symptoms denoting indigestion—namely, flatulence, eructations, etc. Thirst is a symptom usually more or less prominent. Tenderness over the epigastrium and a furred or coated tongue are other symptoms. The urine is high-colored and loaded with the urates. In some cases there is constipation, and in other cases diarrhœa, the latter being due to intestinal indigestion. Pain in the head is a frequent and sometimes a prominent symptom. There may be slight pyrexia, but it is frequently or generally wanting, except after the ingestion of food or stimulants. When transient febrile movement is not thus produced, the pulse is usually feeble and the extremities are cold. There is more or less general debility, but the sense of weakness exceeds the actual reduction of strength. The spirits are depressed, and the suffering may be considerable from malaise without any definite location of pain or distress.

This is a sketch of a class of cases which the practitioner meets with frequently, and which, together with cases of the affection to be considered in another chapter under the name of Acute Dyspepsia, is properly known as a "bilious attack."

If the gastric inflammation be greater, approximating in intensity to acute gastritis, the local and general symptoms are more marked. There is suffering from gastric distress, and sometimes from a dull, obtuse pain in the region of the stomach. The epigastric tenderness is often considerable. Anorexia is complete, with loathing of food and nausea. Vomiting is often a prominent symptom. Mucus is vomited in abundance, and if the efforts of vomiting be prolonged bile is rejected. The patient experiences a temporary sense of relief after vomiting. The feeling is as if the stomach were distended, and acts of vomiting are provoked and aided by voluntary efforts with the idea that if the contents of the stomach were effectually discharged the relief would be permanent. This feeling arises from the inflamed condition of the membrane, and is analogous to the sensation connected with tenesmus in dysentery. It may be called gastric tenesmus. Thirst is generally urgent and cold drinks are craved. The tongue is coated at first, but in the course of the affection it may become clean and reddened. Either constipation or diarrhœa may exist. There is more or less febrile movement, with evening exacerbations, as shown by the pulse and axillary temperature; the latter, however, rarely exceeds 100° F. Chilly sensations and rigors are common, continuing for a few seconds and recurring irregularly. Cephalalgia is generally marked, and in some cases is accompanied by a sense of tension or a feeling as if the head would break. There is often a sense of prostration, with depression of spirits and sometimes a notable degree of mental apathy. In cases of maximum severity subacute gastritis so closely approximates to acute gastritis that there is scarcely a well-marked line of division between the two forms of the disease.

In cases of gastritis with considerable pyrexia the disease is sometimes called "gastric fever." This name implies that the disease is primarily or essentially a fever, whereas the fever is purely symptomatic and secondary to the gastric inflammation.

Subacute gastritis, if the inflammation be slight or moderate, is usually of short duration, convalescence taking place in a few days. If the inflammation have considerable intensity the duration of the disease is from a week to three weeks. If the inflammation persist much beyond the latter date it is to be considered as chronic.

Subacute gastritis in some cases is evidently of dietetic origin. It is sometimes attributable to the decomposition of ingested aliment, owing to a deficiency of gastric juice or to the quantity of food ingested being out of proportion to the digestive capability of the stomach, and to the ingestion of food either difficult of digestion or in which putrefaction had begun prior to its ingestion. Persons who are habitually addicted to over-indulgence in eating, or to highly seasoned dishes and the free use of condiments, are doubtless more liable to this affection than others as a consequence of a gluttonous meal or when from any cause gastric digestion is arrested. The affection sometimes follows a prolonged debauch. The habitual free use of spirits begets a liability to it. It occurs especially among drunkards. It may be caused by any of the acrid or irritant poisons, not taken in sufficient quantity to produce acute gastritis. The so-called uræmic gastritis is caused by the irritant effects of the carbonate of ammonia, formed by the decomposition of urea, upon the gastric mucous membrane; and it is not improbable, as some authors have maintained (Garrod, Charcot), that in some cases of gout, uric acid is eliminated by the stomach, and by a similar irritant effect causes gastritis. In a certain proportion of cases the causes, both remote and proximate, are not apparent.

An affection to which subacute gastritis is closely affiliated is that to be considered under the name of Acute Dyspepsia. Gastric inflammation doubtless enters into certain cases of the latter affection, but the functional disturbance is disproportionately great as compared with the amount of inflammation, and is not to be accounted for by the latter; hence the propriety of considering it as a functional affection of the stomach. The differential diagnosis of these affections is not, practically, of great importance. The symptoms of gastritis are present in certain cases of remittent fever, and perhaps they proceed actually from subacute inflammation of the stomach in these cases. The symptomatic phenomena of remittent fever, however, are sufficiently distinctive to render its discrimination from simple gastritis easy. Cases of ephemeral fever, or febricula, are to be discriminated by the want of proportion between the febrile phenomena and the gastric symptoms. Cases of continued fever, typhus, and typhoid very rarely present symptoms of gastritis with sufficient prominence for the differential diagnosis to be a matter of question. In general, the diagnosis of subacute gastritis is not difficult.

In the TREATMENT of subacute gastritis rest of the inflamed organ is of primary importance. If the inflammation be but slight or moderate, it will suffice to place the patient on a diet reduced in quantity, consisting of milk with lime-water and farinaceous articles. In cases of greater severity complete abstinence for two, three, or four days may be advisable. The vomiting and loathing for food will be likely to secure this end without any injunctions on the part of the physician. In the mean time, if the symptoms denote exhaustion the patient may be supported by rectal alimentation. The abstraction of blood either locally or by venesection is never indicated. Benefit may be derived from sinapisms or a blister over the epigastrium. Emetics and purgatives are contraindicated. The sensations of the patient may lead to a desire for both, especially the former, but they do not effect any desirable object, and their local action upon the inflamed organ will do harm. If the bowels be constipated simple enemas may be employed. Mercury is not indicated, any more than in cases of inflammation affecting the mucous membrane or other portions of the digestive system. On the other hand, remedies to soothe the inflamed membrane and to allay vomiting are indicated—namely, bismuth, hydrocyanic acid, hyoseyamus, and especially the salts of morphia. Small pieces of ice may be swallowed, or iced water given in a small quantity at a time and often repeated, if found to be grate-

ful to the patient. Carbonated water is not only taken with comfort, but appears to be useful.

It is important not to continue the abstinence from food or a great reduction of diet too long. As soon as nutritious articles of food are well tolerated by the stomach they are admissible. The improvement of diet should be made gradually and tentatively. During convalescence the mineral acids are useful as tonics, and after the inflammation has ceased other tonics may be appropriate. Patients who are spirit-drinkers should be told of the connection of the disease with their habits.

Chronic Gastritis.

Chronic gastritis is not infrequent, although it is not as common an affection as was supposed some years ago. Chronic functional disorders were formerly considered as inflammatory. It is not always easy to discriminate clinically between chronic inflammation and the functional affections embraced under the name of dyspepsia. The differential points involved in this discrimination will suffice for the clinical history and diagnosis of the affection. The affection occurs oftener in middle and advanced life than in children and young persons. It occurs in men oftener than in women.

The ANATOMICAL CHANGES in chronic gastritis are most frequently present and most marked in the pyloric region of the stomach. This localization applies also to the majority of morbid processes in the stomach. The color of the mucous membrane varies in different cases. It may be red, brown, ash-gray, slate-colored, or whitish. A bluish-red color, either diffuse or in spots, is usually present in the chronic inflammation attendant upon prolonged passive congestion of the stomach, such as accompanies cirrhosis of the liver, emphysema of the lungs, and heart disease. Ecchymoses and hemorrhagic erosions are frequently present. The mucous membrane, as a rule, is more or less pigmented, and this gives rise to brown, ashy, and slate colors. The pigment generally appears as little dots scattered over the mucous membrane. The same pigmentation often coexists in the intestinal tract. It is most frequent where there is mechanical congestion of the stomach in consequence of portal obstruction. It is referred to alterations in the hæmoglobin of extravasated red blood-corpuscles, and is therefore regarded as a sign of preceding congestion and hemorrhage. The pigment exists in the form of dark granules, either free or in cells, in the intertubular tissue, and sometimes in cells within the tubules. The inner surface of the stomach is coated with a thick layer of viscid mucus or muco-pus. The consistence of the mucous membrane is sometimes peculiarly firm and tough; at other times the membrane is more or less softened. The thickness of the mucous membrane varies in different cases and in different parts of the stomach in the same case. Chronic inflammation leads both to thickening and to thinning of the mucous membrane. The latter result is often, although not invariably, consecutive to the former. The mucous membrane is usually thickened, but not infrequently it is atrophied in certain places, and exceptionally the whole membrane may be abnormally thin. Both in healthy and diseased stomachs the mucous membrane of the pyloric region not infrequently presents little rounded elevations separated by slight furrows. This condition, compared sometimes to granulations upon wounds, is called *mammillation* or *l'état mamelonné* of Louis. When present in healthy (and often in diseased) stomachs it is due to contraction of the muscularis mucosæ (Brücke's muscle). In chronic gastritis, however, it may also be referable to irregular thickening of the mucous membrane. The furrows

may correspond to atrophic spots. Exceptionally, polypoid growths, due to localized increase of connective tissue and enlargement and proliferation of the gastric tubules, are present, even in considerable number (gastritis polyposa). Little cysts about a millimetre in diameter are frequently observed in the mucous membrane. They are the result of distension of parts of the gastric tubules with a clear mucoid secretion. Sometimes the cysts attain a much larger size. The submucous tissue is frequently thicker and denser than normal. There may also be some hypertrophy of the muscular coat. Upon microscopical examination the interstitial tissue of the mucous membrane is usually found to be increased in amount. The gastric tubules may be enlarged in consequence of swelling and parenchymatous or fatty degeneration of their epithelial cells. Usually the tubules are affected in groups, some remaining unchanged. The degenerative change may lead to complete destruction of the epithelial cells. The tubes are then partly or completely filled with albuminous and fatty detritus. Finally, the tubules may become atrophied, and in some places even obliterated. According to W. Fox, fatty degeneration may occur in the connective tissue as well as in the glands. The cystic transformation to which reference has been made is attributable to partial occlusion of the tubules in consequence of the new growth of interstitial tissue. A change which occasionally occurs is proliferation or adenomatous growth of the tubules. In the neighborhood of the pylorus little villous projections of vascularized connective tissue are often met with in chronic gastritis. In the atrophied portions of mucous membrane the tubules are shorter and narrower than normal. Such places have usually a smooth surface and are pigmented.

SYMPTOMS denoting indigestion or difficult digestion are present in cases of chronic gastritis, but these alone are not diagnostic, since they alike exist in cases of dyspepsia. Pain may not be present, and if present it is not distinctive. A burning sensation or a feeling of heat in the gastric region is somewhat diagnostic. Tenderness over the epigastrium is somewhat diagnostic, provided it be limited to that region and constant; that is, not present merely during the process of digestion or when the stomach is distended. Thirst is diagnostic if habitual; that is, present not only during the process of digestion, but at other times. The appetite is much oftener impaired in connection with chronic gastritis than in cases of dyspepsia, the appetite being generally preserved, and often craving, in the latter. The nutrition is oftener defective in cases of chronic gastritis. Dyspeptics often preserve their weight undiminished. In chronic gastritis stimulating articles of food, such as meat and condiments, are not as well borne as bland aliments, the reverse being oftener the case in dyspepsia. Alcoholic and other stimulants produce gastric distress in cases of chronic gastritis, whereas they often relieve distress incident to merely functional disorder. Nausea and vomiting are more likely to occur in connection with chronic gastritis, excluding cases of so-called acute dyspepsia and certain cases of functional disorder characterized by vomiting. In ordinary cases of dyspepsia nausea and vomiting are not common. A slight grade of febrile movement is sometimes observed in chronic gastritis, and very rarely in a purely functional disorder.

The DIAGNOSIS is to be based on the combination of more or less of the foregoing differential points. In making the diagnosis certain structural affections of the stomach are to be excluded—namely, carcinoma and ulcer. The diagnostic symptoms of these affections will be considered in Chapter III.

Chronic gastritis may follow an acute or subacute inflammation of the stomach developed spontaneously or produced by the acrid or corrosive poisons. It

may proceed from excesses in eating or spirit-drinking, and on the other hand it is stated that long fasting or too rigid dieting may give rise to it. In dogs destroyed by starvation Andral found the stomach inflamed and ulcerated; but similar experiments made by Collard de Martigny were negative as regards appearances of inflammation in this organ.¹ Stark, who fell a victim to experiments in dietetics in 1869, had symptoms of gastritis developed during prolonged abstinence. Arsenic introduced into the system by absorption from an external wound gives rise to gastritis, as was ascertained by Brodie and verified by the observations of others. Chronic gastritis also frequently results from long-continued venous congestion of the stomach in consequence of obstacles to the circulation in the liver, lungs, and heart. This chronic congestion is most intense, *ceteris paribus*, when the obstacle is in the liver. Emphysema of the lungs, chronic pleurisy, valvular lesions of the heart, and especially cirrhosis of the liver, are often accompanied by chronic gastritis. It occurs also in connection with gout and with pulmonary phthisis. Chronic gastritis occurs in certain cases of renal disease involving uræmia; the explanation being that already given—namely, that the carbonate of ammonia which is formed from the decomposition of the urea eliminated by the gastric mucous membrane acts as a local irritant.

The first point in the TREATMENT is the removal of dietetic causes which may have originated, or which may tend to perpetuate, the affection. The patient is to be placed on a bland and easily-digested diet, consisting of milk, eggs, stale bread, soft-boiled rice, and other farinaceous articles—articles digested in the small intestine. Meat and stimulants are to be interdicted. For a short time it may be advisable to reduce the quantity of food below the amount which the wants of the system require. Food should be taken in small quantities and at shorter intervals than in health. Moderate counter-irritation over the epigastrium is useful. The remedies to be administered are few. Solicitations for emetics and cathartics are to be resisted. Patients often declare that they are "bilious" or that there exists "foulness of the stomach," and hence that they need evacuant medicines; but in place of medicines which from their irritant action will tend to increase or prolong the inflammation, remedies to soothe the inflamed membrane are indicated—namely, small doses of morphia or codeia, hyoscyamus, hydrocyanic acid, bismuth, etc. [The medicinal treatment of this disease has for its chief objects the assistance of the enfeebled digestion and the suppression or diminution of fermentative processes in the stomach. Both of these indications may be fulfilled by the administration of hydrochloric acid, which not only supplies a deficient element of the gastric juice, but is also a powerful antiseptic. According to Ewald, the quantities of hydrochloric acid usually prescribed are much too small to obtain the best effects from this drug. He bases this opinion upon the large quantities of this acid which are present in the gastric juice in a state of health—viz. from 0.2 to 0.4 per cent. Fifteen drops of dilute acid may be given in water three times after meals, at intervals of fifteen minutes. For the protection of the teeth the acid should be well diluted and taken through a glass tube. Pepsin has been long given in a routine manner in all cases of gastric disease, without reference to its presence or absence in the stomach. In gastric catarrh hydrochloric acid may be completely absent from the gastric juice and pepsin continue present; in fact, it is always present except in cases attended with excessive secretion of mucus and in atrophy of the glandular structure. Under the latter circumstances it should be given freely—for example, in doses of from 10 to 15 grains, dissolved in water acidulated with HCl, fifteen or twenty minutes

¹ Magendie, *Journal de Physiologie*, tome viii.

after meals. These doses of pepsin may seem large in view of the fact that pepsin is a ferment, and, like other "enzymes," exerts its specific effect when present in very small amount. The artificial products are, however, much weaker than the pepsin as secreted by the gastric glands, where it is in its nascent state; and, besides, a certain amount of that prescribed is doubtless lost by entering into unusual combinations and by being propelled prematurely into the duodenum.

Probably the most efficacious therapeutic measure in cases of chronic gastric catarrh is the systematic washing out of the stomach, or, as it is called, *lavage*. The organ is first thoroughly washed out with warm water until the fluid is returned free from particles of food or mucus; then with water to which some antiseptic substance such as borax, sodium salicylate, or common salt is added. Lavage not only cleanses the stomach, but exerts a tonic effect upon the glands and excites them to a more healthy action. As an auxiliary to lavage, or, in case it cannot be employed, as a substitute for it, benefit may be derived from certain antiseptic drugs, such as thymol, creosote, carbolic acid, benzoic acid, and salicylic acid. These substances should be taken shortly before meals, so that the food may enter a stomach that has been rendered more or less aseptic.

There are certain drugs which are believed to exert a direct curative effect upon the diseased mucous membrane, but they are of inferior utility to the above-mentioned measures. The chief of these are bismuth, nitrate of silver, arsenic, and oxide of zinc. It is too much to expect that these drugs, and especially the nitrate of silver, should exert any good effect upon a membrane covered with a tenacious layer of mucus. When this is removed by lavage they may be of service. When the gastritis is secondary to heart disease, cirrhosis of liver, emphysema, or other disturbance of circulation, the treatment must be chiefly addressed to the primary affection.—H.] After the inflammation has ceased functional debility or atony remains. Tonics and improved diet are then required. It is a point of delicacy to determine when to make this change in the treatment. It is like resorting to passive motion in cases of fracture or dislocation. The change is to be begun tentatively, and to be continued or not according to the effect. The symptoms of functional disturbance and the indications for treatment which may be present after the inflammation ceases will be considered in connection with Dyspepsia. (Vide Chapter IV.)

Phlegmonous Gastritis.

By phlegmonous gastritis is understood suppurative inflammation of the walls of the stomach. This disease is very rare. The submucous tissue is primarily involved, but the inflammation may extend to the other coats of the stomach. Synonyms for this disease are gastritis submucosa (Dittrich), suppurative liuitis (Brinton), and interstitial suppurative gastritis (Auvray). The affection appears either as a circumscribed collection of pus in the walls of the stomach or as a diffuse purulent infiltration of the ventricular coats. The former condition, which is the more frequent, is also called abscess of the stomach, which may be single or multiple. It may attain the size of the fist. The purulent collection is in the submucous coat, and it frequently invades the muscular layer. The mucous and serous layers may be intact. There is usually, however, a localized peritonitis over the seat of the abscess. The abscess may rupture through the mucous membrane into the cavity of the stomach, or less frequently through the serous coat into the peritoneal

cavity. In rare instances recovery may take place after the escape of the pus into the cavity of the stomach. A cicatrix then results, and this may lead to stenosis of the stomach.

Purulent infiltration of the submucous coat usually involves only a part of the stomach; it may, however, affect its whole extent. The suppurative process may also extend into the lower part of the œsophagus and into the duodenum. The wall of the affected portion of the stomach is thickened; and it may be six or eight times thicker than normal. The mucous membrane is usually swollen and spongy in texture. It generally presents a number of little round openings, through which pus can be pressed out. Sometimes larger irregular ulcers are present. Upon cutting through the wall of the stomach the accumulation of pus is found to be greatest in the submucous coat, whence purulent septa often extend between the bundles of fibres in the muscular coat. The subserous tissue also frequently contains pus. In fact, while the lax submucous and subserous tissues suffer the most, microscopical examination usually shows the presence of large numbers of pus-cells in the firmer mucous and muscular coats of the stomach. Purulent infiltration may be accompanied by the presence of circumscribed abscesses. The suppurative inflammation exceptionally may not have advanced to the breaking down of tissue, so that the infiltration with pus-corpuscles is evident only upon microscopical examination. Upon microscopical examination, in addition to large quantities of pus-cells, are found many micrococci, which, at least in some cases, are streptococci. Circumscribed inflammation of the serous covering of the stomach (perigastritis) is often present, and not infrequently there is general peritonitis. Infectious thrombi may form in the veins of the stomach, and by the separation of emboli may lead to secondary abscesses in the liver and lungs. Phlegmonous gastritis is one of the causes of suppurative pylephlebitis. In a number of cases there have been evidences of a previous chronic gastritis, with fibrous thickening of the submucosa.

Etiologically, phlegmonous gastritis may be divided into two varieties—a primary, idiopathic; and a secondary, metastatic. Metastatic phlegmonous gastritis, which is usually in the form of circumscribed abscess, is secondary to severe infectious diseases, such as pyæmia and puerperal fever. The primary variety has been observed most frequently in drunkards. Other causes which have been assigned, the efficiency of which is doubtful, are injuries in the region of the stomach, errors in diet, and ulcer of the stomach. In most cases of the primary variety it is impossible to assign an efficient cause. Males are more frequently attacked than females. It has usually occurred in the middle period of life.

The SYMPTOMS of the metastatic variety are usually obscured by those of the primary disease. The idiopathic form generally runs an acute course, terminating in from one to three weeks. Its progress, however, may be chronic and insidious. As a rule, the disease begins with a chill and may be attended by repeated chills. The temperature is elevated, often considerably. The pulse is rapid and feeble. The patient suffers from thirst and anorexia. There are usually severe pain and tenderness in the epigastric region, but these may be absent. Vomiting and retching are prominent symptoms. The stomach is generally more or less distended with gas. In some cases there has been constipation, and in others diarrhœa. Prostration sets in early. Brinton observed icterus in some cases. Toward the end the patient becomes delirious. Death is usually preceded by a state of collapse. The fatal termination is sometimes sudden. These symptoms may be complicated by those of acute peritonitis. As a rule, no pus has been detected with the naked eye in the vomited material. Sometimes, however, when an abscess has burst into the stomach a large quantity of pus has been vomited.

asionally an abscess in the wall of the stomach is of sufficient size to be it during life as a tumor. The duration of the disease is usually from two to ten days, but it may be longer.

There are no diagnostic symptoms of phlegmonous gastritis. Its recognition during life is usually impossible. It may, however, sometimes be suspected by excluding other conditions, especially general peritonitis. In some cases its presence has been rendered probable by the detection of a swelling connected with the stomach, the disappearance of which was followed by the vomiting of a quantity of pus. But even in this case it would be difficult to exclude the rupture of an abscess which had taken its origin outside of the stomach; for instance, a circumscribed collection of pus in the peritoneal cavity.

The termination of phlegmonous gastritis is usually fatal. There is reason, however, to believe that abscess of the stomach may end in recovery.

The TREATMENT indicated in phlegmonous gastritis has for its objects complete rest of the affected organ and the relief of pain. The first of these objects is secured by rectal alimentation and opiates. The relief of pain is effected by the latter in conjunction with emollient and soothing applications over the epigastrium.

Croupous and diphtheritic inflammations of the stomach have been described, but they are little understood and are without clinical interest, being unattended by distinctive symptoms. Pseudo-membranous gastritis is usually secondary to some other disease, such as croup and diphtheria, typhoid fever, pyæmia, or puerperal fever. It may be produced by swallowing acrid poisons.

Chronic Interstitial Gastritis—Cirrhosis of the Stomach—Hypertrophic Stenosis of the Pylorus.

The disease known under these names is characterized by thickening of the walls of the stomach in consequence of new growth of connective tissue. The affection was clearly described by Brinton, who proposed for it the names plastic linitis and cirrhosis of the stomach. It has also been called fibroid degeneration or infiltration, induration, sclerosis, and hypertrophy of the stomach. The name chronic interstitial gastritis implies that the morbid process is a chronic inflammation of the interstitial tissue of the stomach, analogous to that of the liver in cirrhosis. The affection is referred to by most German writers under the name of chronic catarrhal gastritis, with which, although often associated, it should not be confounded. The disease, although rare, has been observed in several typical cases. In such cases the stomach is small and increased in weight and density. The diminution in its capacity may be extreme. Its cavity may not be larger than a medium-sized pear. In certain instances the stomach has been described as normal in size or even dilated. The thickness and increased density of the ventricular walls may be such that upon incision the organ does not collapse. The stomach-wall may measure an inch or more in thickness. The organ may be uniformly affected or the change may be greatest in the pyloric region. When the pyloric region is alone affected the remainder of the stomach is dilated instead of contracted. Upon examining a section through the wall of the stomach the coats are found to present an unnatural uniformity. Their consistence is firm, almost cartilaginous. The new growth of connective tissue, to which the change is mainly due, involves usually all of the coats of the stomach, but especially the submucous, which appears as a dense, white layer. The muscularis, especially the transverse layer, is frequently much hypertrophied, and presents a grayish, translucent appearance. It is usually invaded by the new growth of fibrous tissue.

The subserous tissue is also thickened and fibrous. The serous coat is of peculiar opaque, pearly-white color. The mucous membrane may be intact but it is generally involved in the morbid change. Its interstitial tissue thickened, the tubules are atrophied, and they may even disappear over a considerable extent of the stomach.¹ In some cases no changes in the gastric glands have been noticed.

The thickening is sometimes confined to the neighborhood of the pylorus. This condition has been called fibroid degeneration of the pylorus (Haber-shon) and hypertrophic stenosis of the pylorus (Lebert). In works devoted specially to diseases of the stomach it appropriately receives separate consideration. The thickening here also is due to formation of new fibrous tissue and to hypertrophy of the muscular coat. This lesion induces stricture of the pylorus, which may amount almost to complete closure of the orifice. In consequence of pyloric obstruction, the stomach becomes dilated and its muscular coat is hypertrophied. In a case of hypertrophic stenosis of the pylorus, related by Nauwerk,² the stomach occupied two-thirds of the abdominal cavity. This lesion has been confounded with scirrhus cancer of the pylorus, from which it is to be distinguished only by microscopical examination. In some cases of hard cancer of the stomach the cancerous alveoli are few in number and separated by a large quantity of fibrous tissue.

The symptoms of cirrhotic contraction of the stomach are not sufficiently distinctive to admit of a positive diagnosis. The affection is a grave one, and usually terminates fatally. Sometimes, like other severe affections of the stomach, it is unattended by symptoms. Usually the symptoms at first are those of simple chronic gastritis, such as indigestion, loss of appetite, vomiting, and feeling of oppression in the epigastrium; but these symptoms are inconstant and possess nothing characteristic. As the disease progresses a more severe affection is suspected, usually cancer of the stomach. The patient loses flesh and strength. In an interesting case reported by Nothnagel the patient presented all of the essential symptoms of pernicious anæmia, including hemorrhages in the retina and elsewhere. To a certain degree characteristic of cirrhotic contraction are the inability to take more than a small quantity of food or drink at a time and the sense of fulness which follows the ingestion of this small quantity. The patient thus suffers from inanition, both in consequence of the small capacity of the stomach and from the disturbance of its digestive functions. Sometimes, but not always, a hard mass presenting the contracted contours of the stomach can be felt through the abdominal wall. In a few cases the vomiting of coffee-ground material has been noted, but this occurrence is exceptional. Pain is not usually a prominent symptom. Constipation has been the rule.

In a case under my observation, in which the walls of the stomach were found to be from half an inch to an inch in thickness everywhere except at the pyloric third, the patient up to a few weeks before death supposed that he was simply dyspeptic, his ailments not leading him to seek medical advice. In this case the organ formed a resisting, movable tumor felt through the abdominal walls, and the disease was supposed to be carcinoma.

When the fibroid metamorphosis is confined to the pylorus the symptoms are those of stenosis of the pyloric orifice, combined with dilatation of the stomach. Prominent among these symptoms are vomiting of accumulated ingesta and obstinate constipation. The symptoms are explicable by the obstacle to the entrance of substances from the stomach into the intestine.

¹ In a case reported by Nothnagel, and examined microscopically by W. Müller, glands were found only in the pyloric region (*Deutsches Archiv f. klin. Med.*, 1879, Bd. 24, S. 353).

² *Deutsches Archiv f. klin. Med.*, 1878, Bd. 21, S. 578.

The symptoms and signs of dilatation of the stomach will be considered hereafter. Nauwerk, in the report of the case of hypertrophic stenosis to which reference has been made, gives an interesting example of the length of time during which ingesta may remain in the stomach. He found in the stomach, at the autopsy, cherry-stones which had been swallowed three months previously, and which had remained, although the stomach had been washed out and the patient had vomited repeatedly. Sometimes the thickened pyloric part of the stomach can be felt during life as a small, hard, movable tumor.

The DIAGNOSIS of cirrhotic contraction of the stomach and of hypertrophic stenosis of the pyloric valve cannot usually be made with any degree of certainty. The disease is most likely to be confounded with cancer of the stomach. The following points are to be considered in attempting to reach a probable diagnosis: Cirrhosis of the stomach is often of much longer duration than cancer; it may attack persons much younger than those usually affected with cancer; pain in the region of the stomach and vomiting of blood are less frequent and prominent symptoms in cirrhosis than in cancer; the inability to take more than a small quantity into the stomach is a more marked symptom in cirrhosis than in cancer. Upon no single one of these points, however, can much positive value be placed in a differential diagnosis; nor is too much weight to be placed upon the detection of a hard tumor simulating the contours of the stomach. Such an occurrence is rare and would not suffice to exclude cancer. It has been proposed to determine the size of the stomach by causing the evolution of carbonic acid gas in its cavity, according to the method first proposed by Frerichs (vide *Dilatation of the Stomach*, Chapter III.), but this procedure has not yet been employed in contraction of the stomach, and it could not well serve as a basis of a positive diagnosis. The diagnosis of cirrhosis of the stomach, then, may in certain cases be rendered probable by a combination of favorable circumstances, but it can hardly become a certainty.

The ETIOLOGY of chronic interstitial gastritis is obscure. Most writers concur in regarding spirit-drinking as one of the causes. It is most frequent in men and after forty years of age. It has, however, been met with in temperate persons of either sex and in early life. It is often preceded and accompanied by the symptoms of chronic simple gastritis, but that there is no essential connection between these processes is proven by the infrequency of cirrhosis of the stomach compared with the frequent occurrence of simple chronic gastritis. The prognosis is grave. The disease usually runs a chronic course and terminates by asthenia.

The TREATMENT embraces remedies to palliate irritation of the stomach, abstinence from spirits and other stimulants, careful regulation of diet, and, if there be pyloric obstruction, the means indicated in cases of dilatation of the stomach.

Gastro-Duodenitis—Duodenitis.

In acute gastritis the inflammation, as already stated, may extend into the duodenum. This is also true of subacute and chronic gastritis; but it would appear from the symptoms that subacute duodenitis may occur as a separate affection, not connected on the one hand with gastritis, or on the other hand with inflammation of the lower portion of the small intestine. The symptoms are—obscure pain, uneasiness or distress occurring some hours after the ingestion of food—that is, after it passes from the stomach into the duodenum—and tenderness below the epigastrium and over the site of the affected organ. Duodenitis, occurring either separately or in connection with gastritis and enteritis, is interesting and important as standing in a causative relation to jaundice. The jaundice is to be explained by obstruction either

from swelling of the mucous membrane of the duodenum at the opening of the ductus choledochus or from an extension of the inflammation into the duct. A plug of mucus is frequently found in the ductus communis near its opening into the duodenum. The treatment is the same as that of subacute gastritis. The affection will again be referred to in the consideration of Jaundice.

It is a curious fact, first ascertained by Curling and confirmed by other observers, that a sloughing ulcer sometimes forms at the upper part of the duodenum within a few days after the occurrence of a severe burn of the skin. Perforation may occur under these circumstances. Ulceration of the duodenum, however, is by no means a constant effect of an extensive burn.

CHAPTER III.

STRUCTURAL DISEASES OF THE STOMACH.

Softening.—Gastric Ulcer.—Carcinoma of the Stomach.—Dilatation of the Stomach.—
Degeneration of the Gastric Tubes.—Waxy Degeneration of the Stomach.

Softening of the Stomach—Gastromalacia.

SOFTENING of the mucous tunic of the stomach has been already mentioned as one of the anatomical characters of gastritis. The importance of not considering mere softening as an evidence of inflammation was then dwelt upon. At autopsies softening of the mucous membrane of the fundus is very often found. Softening may, however, be much more extensive. Not only may it involve the entire inner surface of the stomach, but it may extend in depth so as to affect the remaining coats of the stomach, and it may even lead to perforation of the stomach and the escape of its contents. Nor does the process always stop there. The adjoining organs may be attacked and undergo a similar softening. Thus the liver may be partially destroyed, or the diaphragm may be perforated and the contents of the stomach be found in one of the pleural cavities. There has been much controversy as to the nature of this softening, but it is now admitted that it is a post-mortem occurrence due to self-digestion. It has been rendered probable by the experiments of Pavy that the stomach is protected during life from self-digestion by the alkalinity of the blood circulating in its walls. The alkaline blood, which flows in an especially rich network of capillaries in the superficial layers of the mucous membrane, neutralizes the acid of any of the gastric juice which may penetrate the mucous membrane. With death the neutralizing influence of the circulating blood ceases. If the stomach now contain a sufficient quantity of gastric juice, and if the temperature be suitable, there is nothing to prevent the digestion of this organ and the extension of the digestive process to surrounding parts. Inasmuch as softening of the stomach, in the traditional acceptance of this term, is purely a post-mortem process, it cannot claim consideration in works the purpose of which is chiefly clinical. Fuller descriptions of this process are to be sought in books on pathological anatomy and on physiology.

Gastric Ulcer.

The form of ulcer to be here considered constitutes one of the most frequent and dangerous of the diseases of the stomach. It is to be distinguished from certain ulcerations which sometimes occur in connection with inflammation of the stomach—namely, the so-called catarrhal ulcers, follicular ulcers, and superficial hemorrhagic erosions. To these conditions, as well as to ulcerations produced by corrosive poisons, reference has already been made. Genuine tuberculous ulcers occur in the stomach, but they are very rare and require no further mention. [The last remarks are also applicable to typhoid ulceration of the stomach.—H.]

To the form of ulcer now under consideration various designations have been applied, such as simple (in distinction from cancerous), chronic (a term not always applicable), round, perforating, eroding, and digestive (*ulcus ventriculi simplex, chronicum, rotundum, perforans, corrosivum, ex digestionem*). Simple ulcer of the stomach presents certain ANATOMICAL CHARACTERS which are met with elsewhere only in a similar form of ulcer in the lower part of the œsophagus and in the upper part of the small intestine.¹ The most marked of these peculiarities is that in its early stages the ulcer presents no evidences of inflammation in its base or its edges. The shape of the ulcer is round or oval, and sometimes, but rarely, irregular from the coalescence of two or more ulcers. The floor of the ulcer usually lies deeper than the mucous coat. From its tendency to extend in depth the ulcer is called perforating. The floor is not infrequently the muscular tunic; but it may be the serous coat, or, if the ulcer have perforated the walls of the stomach and adhesions have formed, the base of the ulcer may be occupied by some of the adjacent viscera, such as the pancreas or liver. As the ulcer extends in depth each successive tunic of the stomach is invaded in less extent than the preceding. The ulcer thus acquires a characteristic funnel-shape, the large opening being in the mucous membrane and the apex directed toward the peritoneum. The successive layers can sometimes be recognized as strata or steps in the wall of the ulcer. This funnel-shaped appearance is not always present. The edges are sometimes abrupt instead of sloping. If the ulcer be recent, its edges are smooth and clean-cut like those of a hole punched out of the mucous membrane. They may be infiltrated with blood, but they are not swollen by inflammatory exudation. The base may be smooth or soft and pulpy, and it may also have a hemorrhagic aspect. More frequently, old ulcers are found in which the edges are somewhat thickened and indurated by the growth of fibrous tissue. The floor in old ulcers is usually smooth, pale, and hard. Chronic gastritis is not infrequently present. The size of the ulcer varies much in different cases. The average size is perhaps that of a silver dime or quarter of a dollar. The ulcer may be very minute. In two cases reported by Murchison pore-like holes from one to two lines in diameter were found, which had penetrated one of the gastric arteries and produced fatal hemorrhage. A similar case has been reported by Reid.² On the other hand, the ulcer may be as large as the palm of the hand, and may extend along the lesser curvature from the pyloric to the cardiac orifice.³ As a rule, only a single ulcer is found, but it is not a great rarity to find two or more ulcers (according to Brinton, in 21 per cent. of the cases). Still less infrequent is it to meet

¹ This is true, unless the rare variety of ulcer described by Clarke and by Klebs as *ulcus corrodens uteri*—corroding ulcer of the cervix uteri—be included in this category. (Consult Klebs, *Handbuch der Pathologischen Anatomie*, Bd. 1, S. 873.)

² *Buffalo Medical Journal*, 1846, vol. ii. p. 641.

³ Cruveilhier has described an ulcer $6\frac{1}{2}$ inches long and $3\frac{1}{2}$ wide; Law, one measuring 6 by 3 inches.

with the cicatrices of old ulcers. Sometimes ulcers are found opposite each other on corresponding parts of the stomach. The most frequent seat of gastric ulcer is in the pyloric region on the posterior surface and in the immediate neighborhood of the lesser curvature.¹ Ulcers of the anterior surface are much rarer, but are more dangerous, as will be explained presently. The microscopic examination of ulcers still progressing shows in their base and edges a granular substance which is the result of molecular disintegration of the surrounding tissue. It is by a process of molecular necrosis that the ulcer extends. In rare instances granulation-tissue may be present in the wall of the ulcer. In the ulcers with hard, thickened edges, these as well as the base are occupied by fibrous tissue containing fusiform and round cells; the blood-vessels in this tissue present thickened walls and diminished calibre; and they may contain thrombi. Newly-formed connective tissue may extend for some distance into the surrounding mucous membrane and compress the tubules, which may be thereby distorted and even obliterated. Simple ulcer may be complicated by cancer of the stomach. In fact, some writers believe that ulcer may even predispose to the development of cancer.

Ulcer of the stomach not infrequently heals by cicatrization; in fact, cicatrices are found oftener than open ulcers. The resulting cicatrix is usually a whitish stellate scar, attended with puckering of the adjacent mucous membrane. If the ulcer be large and deep, cicatrization may cause considerable, and even extreme, deformity of the stomach. Thus the stomach may be constricted so as to present an hour-glass shape. Stricture of the pylorus, with consequent dilatation of the stomach, may be caused by cicatrization of an ulcer; but instead of cicatrizing the ulcer may penetrate all of the coats of the stomach. When the ulcer is situated on the posterior surface of the stomach, as is usually the case, a localized peritonitis over the seat of the ulcer generally leads to the formation of adhesions with surrounding organs, so that when perforation is effected the floor of the ulcer is formed by some part adjacent to the stomach. Sometimes, however, the development and the progress of the ulcer are so rapid that time is not allowed for the formation of adhesions, and the contents of the stomach escape into the peritoneal cavity. It is a noteworthy fact that ulcers on the anterior surface, although the least frequent, are the most liable to perforate without protective adhesions. The explanation of this peculiar danger lies in the active movements of this part of the stomach and its unfavorable relations to surrounding parts. The pancreas most frequently forms the floor of ulcers situated on the posterior surface, but the stomach may also become agglutinated to the liver, the spleen, the diaphragm, lymph-glands, etc. The ulcer may continue to extend into the surrounding organs which form its base. The pancreas usually offers considerable resistance to the progress of the ulcer, but the liver is not infrequently invaded. The funnel-shaped appearance is not preserved in the organs secondarily involved. On the other hand, cavities of considerable size may be formed which communicate by a small opening with the stomach. The reactive inflammation in organs invaded by gastric ulcer leads to the formation of fibrous tissue, and sometimes, particularly in the liver, to abscesses. Fistulous communications of the stomach with adjacent parts may be formed. Thus the ulcer may open into the colon, the duodenum or some other part of the intestine, the pleural cavity, the lungs, or the gall-bladder. Gastro-cutaneous fistulae may be produced, but they are very rare. The most frequent are gastro-colic fistulae. If the ulcer open

¹ Of 793 ulcers, in 288 the ulcer occupied the lesser curvature; in 235, the posterior wall; in 95, the pylorus; in 69, the anterior wall; in 50, the cardia; in 29, the fundus; in 27, the greater curvature (article by Welch on "Gastric Ulcer," in *Pepper's System of Practical Medicine, by American Authors*, vol. ii.).

to the peritoneal cavity—and this accident may take place even after adhesions are formed—peritonitis ensues if immediate death do not follow. Death sometimes occurs suddenly from perforation of the stomach, and is attributed to paralysis of the heart from shock. The peritonitis following perforation is usually general. It is sometimes, however, localized, in consequence either of the slow escape of the gaseous and fluid contents of the stomach through a small opening or of the formation of previous adhesions. On p. 57 reference has been made to subphrenic abscesses containing air and simulating pneumo-pyothorax. The external opening in the stomach is usually round, and its edges are sharp and well defined in cases of perforation.

The hemorrhages which constitute one of the chief dangers to life in gastric ulcer may proceed from capillaries and small vessels in the walls or base of the ulcer, or they may come from erosion of a large artery or vein. In cases of profuse fatal hæmatemesis an eroded artery will generally be found in the floor of the ulcer. The ulcerated artery may be either one of the arteries of the stomach or an adjacent vessel, as the splenic. Gastric ulcer has been known to perforate the portal vein, and in more than one instance a simple or a suppurative pylophlebitis has been produced by this disease. In several cases small aneurisms have been found in the floor of the ulcer.

The *pathogenesis* of simple ulcer of the stomach has been a subject of much experimentation and discussion. The absence of inflammation, and the fact that this variety of ulcer is met with only in the lower part of the œsophagus, the stomach, and the upper part of the small intestine, early suggested the view that it is produced by the solvent action of the gastric juice; and this is the opinion now generally entertained. Hence the names peptic ulcer, digestive ulcer, and *ulcus ex digestionem* are sometimes employed. In the preceding article was stated Pavy's view, which is widely accepted, that self-digestion of the stomach is prevented during life by the constant flow of alkaline blood in the rich capillary network of the gastric mucous membrane. If this view be adopted, it must be assumed that the primary cause of simple gastric ulcer is to be found in some local disturbance of the circulation in the gastric mucous membrane. As to this also most writers are agreed. As to the nature, however, of the change thus interfering with the circulation there is the widest diversity of opinion. An absolute basis of fact is lacking for nearly all the theories propounded to explain the diminished resistance of the mucous membrane to the action of the gastric juice. The anatomical investigation of the ulcer as a rule furnishes little or no clue to its primary cause. The following conditions have been assigned as causes of gastric ulcer by interfering with the circulation and consequently diminishing the alkalinity of circumscribed portions of the wall of the stomach: Embolism and thrombosis of branches of the gastric arteries; thrombosis of the corresponding veins; diseases of the coats of the same vessels, especially atheroma, fatty degeneration, and amyloid degeneration; spasm of the arteries, causing anemia of the districts they supply; spasm of the muscular coat of the stomach, compressing the veins and leading to hemorrhages; obstructions in the portal circulation, inducing chronic congestion and hemorrhages from the gastric veins; hemorrhages into the wall of the stomach from rupture of the vessels incident to injuries, vomiting, ingestion of corrosive substances, increased blood-pressure, and aneurismal and varicose dilatations; inflammatory infiltration compressing the blood-vessels. Disturbed nervous influence is also been adduced as a cause.¹ Böttcher's view, that gastric ulcer is of

In support of this view have been cited the experiment of Frerichs, who found an ulcer of the stomach in a cat after division of the splanchnic nerves and of the celiac plexus, and the experiments of Ebstein, who by injuries to the brain and cord in animals induced ulcers upon a hemorrhagic base. A not very appropriate comparison has also been made between gastric ulcer and ulcer of the cornea after section of the trigeminus.

mycotic origin and produced by the action of micrococci, has met with no confirmation. Finally, increased acidity of the gastric juice has been thought to be an element in the causation of digestive ulcer. It would lead too far to attempt a criticism of these different theories. The embolic origin is naturally suggested by the funnel shape of the ulcer corresponding to the wedge-shaped area of distribution of branches of the gastric arteries, but this theory is almost wholly devoid of anatomical support. No embolus in a gastric artery is found in ulcer of the stomach, and in the majority of cases there is no source for an embolus.¹ Gastric ulcer is by no means a frequent occurrence in disease attended by embolism in various parts of the body. If a thrombus be found in a vessel near a gastric ulcer, it is as proper to consider it the effect as the cause of the ulcer. The most plausible view, and the one which has the greatest number of supporters, is that a considerable number of ulcers of the stomach are produced by hemorrhagic infiltration of a circumscribed portion of the wall of the stomach. It is to be noted, as pointed out especially by Axel Key, that the hemorrhage must involve more than the superficial layer of the mucous membrane—must extend probably to the deeper and less vascular tissues. Superficial hemorrhages are followed by superficial erosions, the extension of which in depth is arrested by the great vascularity of the mucous membrane. The mode of production of hemorrhagic erosion is thus similar to that of simple ulcer. The causes of these deeper hemorrhages are doubtless various, and they include many of the causes of ulcer which have been enumerated. Perhaps spasm of the muscular fibres of the stomach attendant upon cardialgia and vomiting should be specially mentioned; but, while considering hemorrhage in the coats of the stomach as a probable, and perhaps frequent, cause of ulcer, it is not necessary to consider it the only cause, or to deny the efficacy of other causes which have been cited, the importance of which, with our present knowledge, is less evident. It is interesting that ulcers which may be produced in various ways artificially in the stomachs of animals readily heal. Anæmia, however, has been proven experimentally to be an obstacle to the process of repair. From this point of view the problem is quite as much to explain why ulcer of the stomach does not heal as it is to explain how it is produced. It is probable that various constitutional conditions, and also diseases of the blood vessels in the walls of the ulcer, impede the process of repair. [Recent researches have demonstrated that gastric ulcer has for its etiological basis a disproportion between the composition of the gastric juice and that of the blood, consisting in an impoverishment of the latter fluid and a hyperacid state of the former. Of these concurrent causes, the alteration of the blood is the more important because ulcer has been observed in association with a gastric juice of normal acidity. Under such circumstances, which are exceptional, we are justified in assuming that the nutrition of the gastric mucosa is impaired in such a extent that so far as its powers of resisting corrosion by the gastric juice are concerned the latter fluid is *relatively* *hyperacid*.] (Key.)

Two varieties of gastric ulcer are differentiated. Open gastric ulcer is found in the stomach of man and animals as the result of various causes. Chronicities are found in the human species, and in the lower animals. Statistics appear to show a marked increase in the incidence of gastric ulcer in certain geographical situations. In the human species, gastric ulcer is more frequent in men than in many parts of the world.

It was first described by Cruveilhier in the New York Entomological Society in 1877, a case of gastric ulcer in a dog, in which the pyloric artery leading to an ulcer. No gastric ulcer was observed in the stomach.

The CLINICAL HISTORY embraces as the most prominent symptoms pain, tenderness on pressure, vomiting, and hemorrhage from the stomach. These are the important symptoms in a diagnostic point of view. Pain is rarely wanting. It is burning or gnawing in character, coming on directly or soon after the ingestion of food, and continuing until the contents of the stomach have either passed into the duodenum or been ejected by vomiting. The quickness with which the pain follows the ingestion of food is a diagnostic point. If pain be due to simple indigestion or neuralgia, it generally occurs after a greater or less interval from the time of taking food. It is situated at or near the epigastrium, and is generally confined to a small space. A similar gnawing pain in the back, between the shoulders, is not uncommon. The probable cause of the pain is irritation of the ulcerated space by the contact of the ingesta and the gastric juice. The pain from this cause is especially marked after the ingestion of stimulating articles of food or drink, and when, from indigestion, the contents of the stomach undergo chemical changes. Pain may be caused also by circumscribed peritonitis and by the traction of adhesions which have resulted from peritoneal inflammation. The latter causes may account for the exceptional occurrence of pain irrespective of the ingestion of food. The pain caused by the action of the gastric juice is felt directly after eating, because the secretion of the juice is excited by the presence of food in the stomach. The pain is sometimes absent for several consecutive days. It is affected by the position of the body, being in some cases increased by lying on the back and relieved by bending forward; in other cases the reverse is observed. The explanation is afforded by the situation of the ulcer on the posterior or the anterior wall of the stomach. As in the majority of cases the ulcer is on the posterior wall, relief is oftener obtained by bending forward than by recumbency on the back. Tenderness on pressure over the epigastrium is almost invariably present, confined, like the pain, within a small area, and varying considerably in degree in different cases. Vomiting is a very frequent but not a constant symptom, occurring after a period from the time of taking food varying in different cases, the act of vomiting usually not violent but complete, and the ejection of the contents of the stomach followed by notable relief of pain and distress. Mucus may be expelled in more or less abundance with the ingesta. As respects vomiting, much will depend on the quantity and kind of food ingested. Indigestible and stimulating articles are more likely to provoke it, as well as to increase pain, than those which are bland and easy of digestion. Hot substances are not as well borne as cold. Hemorrhage, as shown by the vomiting of blood in greater or less quantity, is a symptom of frequent occurrence. The vomiting of blood generally occurs after a meal. The hemorrhage is sometimes so abundant that life is lost from this cause. Cases have been reported in which life was lost from hemorrhage, although no blood was vomited, the stomach being found, after death, filled with clots. The blood vomited is dark or grumous from the change of hæmoglobin to hæmatin by the action of the gastric juice, provided the vomiting do not immediately follow the hemorrhage. If vomiting quickly follow a profuse hemorrhage, the blood may retain its alkaline reaction and its arterial color. As a rule, simple inspection of the vomited matter suffices to determine the presence or the absence of blood. In cases of doubt resort may be had to microscopic or spectroscopic examination. Blood-corpuscles, usually much shrivelled, can generally be recognized by the microscope. Sometimes, however, they are so disorganized by the action of the gastric juice that their detection by this instrument is difficult or impossible. In this case the spectroscope will usually afford the desired information. The stools also should be examined with reference to

the gross and microscopical appearances of blood, since hemorrhage may take place without vomiting, the blood passing into the intestinal canal.

The bowels in cases of gastric ulcer are generally constipated, a symptom easily understood in the cases in which vomiting is a prominent symptom. Amenorrhœa is common. There is, however, little foundation for the idea that hemorrhage from the ulcer occurs vicariously in the place of menstruation, but the latter ceases or is deficient, as in cases of anæmia produced by hemorrhages elsewhere or from other causes.

The perforating ulcer occurs oftenest in young girls, and particularly in young maid-servants. Statistics show that females are more liable to ulcer, the proportion being 2 males to 3 females. In females the ulcer most frequently develops between twenty and thirty, and in males between thirty and forty, years of age. Clinical observation fails to show any dependence on particular habits of diet or other causes, nor has it any known relationship with other affections. It may be stated, however, that persons of feeble or impaired constitution are more liable to it than the robust.

The DIAGNOSIS of gastric ulcer may be made with much certainty, provided the diagnostic symptoms be present—namely, pain of a burning or gnawing character limited to a circumscribed space in the epigastrium, with tenderness, also circumscribed, the pain felt directly after the ingestion of food, and especially after certain kinds of food, vomiting occurring during the process of stomach digestion, and followed by relief, and, finally, gastrorrhagia or hæmatemesis. Analogous symptoms, it is true, may be present in cases of cancer of the stomach, but there are points of contrast involved in this differential diagnosis which will be noticed presently in considering cancer. Moreover, the absence of a tumor appreciable through the abdominal walls goes far toward the exclusion of cancer. Chronic gastritis and ulcer have symptoms to some extent in common; but in chronic gastritis pain is less prominent, vomiting does not occur so frequently, and hemorrhage is wanting. In cases of gastralgia the pain might suggest the idea of ulcer; but the pain in gastralgia is not aggravated, and, on the contrary, is often relieved, by the ingestion of food; tenderness over the epigastrium is not present, but the pain is often relieved by pressure; vomiting is an occasional symptom only; hæmatemesis does not occur. Attacks of gastralgia and gastric ulcer are, however, sometimes associated. In cases of merely functional disorder pain, vomiting, and hæmatemesis are all wanting. Hæmatemesis, it is to be borne in mind, is not alone evidence of ulcer. It occurs, irrespective of disease of the stomach, in certain cases of cirrhosis of the liver. It is the union of the several symptoms just named that renders the diagnosis complete. These diagnostic symptoms, however, are not united in all cases of gastric ulcer. Hemorrhage is not invariably present; vomiting is not always a prominent symptom, and may be wanting; pain and tenderness are not in all cases marked: the affection, in short, is sometimes latent, more or less difficulty or disturbance of digestion only being manifested. Under these circumstances a positive diagnosis cannot be made. A strong suspicion of the existence of the affection may in some cases be reasonably entertained when the symptoms do not warrant a positive diagnosis.

[The affections with which gastric ulcer is most apt to be confounded are gastralgia nervosa and cancer. The pain attending the former bears no constant relation to the ingestion of food—in fact, as above stated, is sometimes relieved by eating as well as by pressure upon the epigastrium—and is usually associated with other neuroses, such as cephalalgia, intercostal neuralgia, and clavus.

Cancer usually occurs at an age more advanced than that of most of the sufferers from ulcer, and is characterized by the rapid development of pro-

found cachexia, the frequent enlargement of the left supraclavicular glands, the occasional presence of a palpable tumor in the epigastrium or its immediate neighborhood, the absence of free hydrochloric acid from the gastric juice, and the abundant presence of organic acids in that fluid. Hæmatemesis, when present in cases of cancer, is generally small in amount and frequently recurrent. The blood is also more apt to be altered by a prolonged stay in the dilated stomach—coffee-ground vomit.

Ewald gives an elaborate table in which the chief differential diagnostic points between nervous gastralgia, ulcer, and carcinoma are given with considerable detail, but he detracts somewhat from its value by the statement that the features of the three diseases are much more easily defined on paper than in actual practice—an opinion from which no experienced physician will dissent.—H.]

Gastric ulcer proves fatal in different modes. One of these is by perforation, diffuse peritonitis being induced by the escape of the contents of the stomach. Perforation into the general peritoneal cavity occurs in about 6½ per cent. of all cases of gastric ulcer. In the great majority of cases diffuse peritonitis caused by perforation of the stomach proves fatal. Recovery, however, is within the range of possibility. This accident would take place oftener than it does were it not for the adhesion of the stomach to the adjacent organs as a result of circumscribed peritonitis. Perforation is most likely to occur when the ulcer is situated on the anterior surface of the stomach. The perforation generally takes place after the ingestion of a meal, or in the act of straining or sneezing, or in some sudden and forcible movement of the body. In some cases peritonitis, following perforation, occurs without having been preceded by any symptoms pointing to the existence of ulceration of the stomach. The following case is illustrative of the statement just made: A well-nourished woman of about thirty-five years of age had complained only of indigestion, when suddenly there occurred severe abdominal pain, followed by speedy collapse and death. Poisoning was suspected, and the autopsy was made by direction of the coroner. A round, funnel-shaped ulcer of the size of a quarter of a dollar was found on the anterior wall of the stomach. Perforation had taken place and given rise to acute peritonitis. As has been stated, peritoneal adhesions having previously taken place, perforation may open a communication with the transverse colon. The evidence of this is stercoraceous vomiting.

Another mode in which it proves fatal is by hemorrhage. Life may be slowly destroyed by the continued escape of blood or by repeated attacks of hemorrhage, or the loss of blood may be so rapid as to destroy life quickly. Death from hemorrhage occurs in from 3 to 5 per cent. of all cases of gastric ulcer.

Another mode in which it proves fatal is by inanition. Death takes place by slow asthenia when the stomach is so intolerant of ingesta that aliment sufficient for the support of life is not retained. In other words, patients are gradually starved to death, provided life be not cut off by some other disease which the system may be rendered unable to resist in consequence of the debility incident to the stomach affection.

The duration is very variable. Death sometimes takes place from perforation or hemorrhage within a few weeks, or even a few days, after the time when the symptoms first denoted gastric trouble; or, as already stated, perforation and hemorrhage may occur when previous symptoms denoting gastric ulcer were wanting. But if these accidents do not prove the immediate cause of death, life is usually prolonged for many months, and it may be for many years. Brinton states that he has notes of one case in which probably a continuous open ulcer existed for thirty-five years, and of two cases in which

the duration was thirty years, together with three or four of twenty, four or five of fifteen, and several of ten, seven, five, and four years' duration. It is not uncommon for the symptoms from time to time to subside or to disappear, and subsequently to return. These remissions are probably due to healing of the ulcer, which afterward again opens; in other words, relapses are liable to occur.

Gastric ulcer, although a serious affection, is by no means incurable. The mortality is estimated by Welch as about 15 per cent. In consequence of the various disturbances resulting from cicatricial contraction of an ulcer, gastric symptoms may remain after the ulcer has healed in the anatomical sense.

The TREATMENT of gastric ulcer embraces the following objects: *First*, and most important, securing for the stomach absolute rest; and *second*, the arrest of hemorrhage and the palliation of pain. Rest of the stomach is secured most effectually by resorting to rectal alimentation. This is advisable whenever symptoms render the diagnosis of gastric ulcer probable. It is now well established that not only life, but complete satisfaction of the sense of hunger and fair nutrition, may be maintained indefinitely by the introduction of food into the rectum. Indeed, an increase of weight under an exclusively rectal diet has been observed. I can bear testimony to the prompt success of this method of treatment. The kinds of food to be employed and the practical rules to be observed are the same as in the treatment of acute gastritis. (Vide p. 338.) When the stomach tolerates food—that is, when pain and vomiting are no longer caused by ingesta *per os*—the diet should consist for a time of milk, [which may continue the sole article of diet for one, two, or more weeks. It should be administered warm and mingled with lime-water in the proportion of $\frac{1}{2}$ ounce of the latter to 4 or 6 ounces of the former, or, if the gastric secretions are very acid, a little bicarbonate of sodium may be added. It is preferable, however, to increase the proportion of lime-water, as the evolution of gas which follows the administration of the bicarbonate may distend the stomach to an injurious extent. In some cases the milk is better digested when boiled. If milk is found to coagulate in hard curds which are vomited, or otherwise to disagree with the patient, a trial may be made of buttermilk, which is an excellent substitute. The formation of hard indigestible curd in a hyperacid stomach may sometimes be prevented by adding to the milk a little flour previously well boiled with milk or water, or a small quantity of oat-meal or corn-meal gruel; or, finally, the milk may be peptonized. Raw or soft-boiled eggs, beef-, mutton-, or chicken-broth, and good preparations of beef-peptone are excellent articles of diet in these cases. The approaches are thus made to a solid diet which is not resumed until several weeks after the beginning of treatment. Even then the greatest care must be taken for months afterward to exclude indigestible articles of diet.—H.] Considering the frequency of relapses, care to adjust the diet to the digestive power is advisable for a considerable period.

Hemorrhage is to be arrested by small pieces of ice swallowed, and by the application of cold to the epigastrium if the loss of blood be considerable. The fluid extract of ergot may be given *per enema*. Pain may require the use of opiates, the form selected being that which is found on trial to be the least objectionable. [Opium not only relieves pain, but obtunds the sense of hunger, quiets the muscular layer of the stomach, and so prevents or diminishes vomiting.—H.] Opiates may be administered either by the rectum or hypodermically. Pain and vomiting cease generally to be prominent symptoms if complete rest of the stomach be secured by rectal alimentation, so that the laudanum added to the nutritive injections suffices.

It is doubtful whether any remedies exert a direct effect to promote cicatrization. The nitrate of silver and other remedies have been given with

the expectation that they will exert a topical effect upon the ulcer. Clinical observation appears not to furnish evidence of their utility in this way. Gastric ulceration is promoted indirectly by remedies which arrest the peristaltic movements of the stomach and quiet the irritability of the organ; in other words, remedies which have reference to the first object of treatment—namely, securing rest.

Carcinoma of the Stomach.

Most of the tumors met with in other parts of the body may also occur in the wall of the stomach—fibroma, lipoma, sarcoma, myoma, gumma, tubercle, papilloma, adenoma, and carcinoma. Of these, only carcinoma possesses clinical importance.

Next to the uterus, the stomach is the most frequent seat of primary carcinoma.¹ Secondary cancer has also been met with in this organ, but it is rare. The forms of carcinoma of the stomach are scirrhus (fibrous), medullary (encephaloid), colloid (alveolar), and cylindrical-celled epithelioma. Of these, colloid is by far the least frequent. As the distinction between scirrhus and medullary cancer is based upon the difference in consistence, the former being hard and the latter soft, and as all degrees of combination and of transition exist between the two, statistics as to the frequency of the one or of the other are only of limited value. Combinations of hard and of soft cancer and tumors of medium consistence are more frequent than either the very hard or the very soft varieties. Cylindrical-celled epithelioma is a common form of gastric carcinoma—according to some authors, the most common. The most frequent seat of cancer is the pyloric region. The posterior surface and the lesser curvature are more frequently affected than the opposite regions. The cardia is affected in about 8 per cent. of all cases.² Scirrhus cancer is characterized by the large amount of fibrous stroma and comparatively small development of cancerous alveoli. In the great majority of cases it is situated near the pylorus, where it sometimes appears as a partial or complete ring constricting the pyloric orifice. Scirrhus may appear either infiltrated or in the form of distinct nodules. In medullary cancer the spaces filled with cancer-cells predominate over the stroma, which is usually richly infiltrated with round cells. This variety grows more rapidly and is more likely to be attended by metastases than the preceding. It forms a soft tumor, readily ulcerating, and sometimes presenting fungous or villous excrescences upon its surface (so-called villous cancer). Colloid cancer is rare. It may be combined in a nodular form with one of the other varieties, or it may appear as a diffuse thickening of the walls of the stomach, involving apparently its deeper coats. In the latter case the peritoneum, as a rule, is extensively affected by the same process. This species of cancer is readily recognized by the clear, gelatinous substance found in its large alveoli. In cylindrical-celled epithelioma the alveolar structure conforms more closely than in the other varieties of cancer to the type of the normal gastric tubules. The cells contained in the alveoli, more particularly those which line the walls of the alveoli, are cylindrical in shape. In consistence this variety resembles medullary cancer.

The opinion was formerly held that cancer of the stomach develops primarily in the submucous tissue and invades secondarily the other coats of

¹ Of 31,482 primary cases of cancers collected by Welch, the stomach was the seat of the cancer in 21.4 per cent., and the uterus, in 29.5 per cent. (*Pepper's System of Practical Medicine, by American Authors*, vol. ii. p. 533).

² Welch's analysis of 1300 cases of cancer of the stomach gives—pyloric region, 60.8 per cent.; lesser curvature, 11.4; cardia, 8; posterior wall, 5.2; the whole or greater part of stomach, 4.7; multiple tumors, 3.5; greater curvature, 2.6; anterior wall, 2.3; and fundus, 1.5 per cent.

the stomach. Since Waldeyer's view as to the epithelial origin of cancer cells has been so widely accepted, it has been the teaching of many writers that carcinoma develops primarily in the mucous membrane. The process, as described by Waldeyer, is briefly as follows: A group of tubules (from ten to twenty) enlarge, lengthen, and give off offshoots. They are filled with cells resembling usually the adénomorphous variety, but more granular and more deeply staining. The growth of the tubules with their branching offshoots is downward through the muscularis mucosæ. When the lax submucosa is reached the progress is more rapid. Groups of cancer-cells now push their way in all directions, chiefly in the lymphatic vessels and spaces. Cancerous masses penetrate between the bundles of smooth muscular tissue, and often extend to the subserous and serous coats. The growth may be so much more extensive in the submucous coat that the tumor appears to originate there, but according to Waldeyer careful microscopical examination will always disclose some band of connection with the tubules of the mucous membrane. The growth, however, may from the first involve chiefly the mucous coat, and in any case this is, as a rule, sooner or later extensively invaded.

It has already been mentioned that cancer of the stomach may appear in a diffuse or in a nodular form, also as a ring, especially about the pylorus. Ulceration is a frequent occurrence. This is the rule with medullary and cylindrical epithelial, and is not infrequent with scirrhus cancer. There is less tendency to ulceration in colloid cancer than in the other varieties. Ulceration is not always to be regarded as an unfavorable occurrence. The soft cancers especially may be much reduced in size by this destructive process. This reduction may relieve an existing stenosis of the pyloric or cardiac orifice. The shape of the ulcer, particularly when the cancer is medullary, has been often compared to that of a crater—a peripheral wall of cancerous tissue surrounding a central loss of substance. Exceptionally, in cases of scirrhus the ulcer may bear much resemblance to simple or round ulcer with indurated walls; and this fact is to be considered in weighing the statements of those who report many cases of cancer developing from round ulcer.¹ Scirrhus cancer often contains considerable cicatricial tissue, but there is no positive reason to believe that it ever heals. The muscular coat in the neighborhood of cancerous growths is almost always hypertrophied. If the tumor produce stenosis of the pylorus, the rest of the organ is dilated; if the cardiac orifice be constricted, the stomach is reduced in size. Chronic gastritis is a frequent attendant upon cancer. Chronic circumscribed peritonitis, with the formation of adhesions, is common in the neighborhood of the cancer. The wall of the stomach may be perforated by cancerous ulceration leading to invasion of the surrounding organs, to perforative peritonitis, or to fistulous communications. Peritonitis from perforation is less frequent with cancerous than with simple ulcer.² The erosion of large vessels is also less frequent in cancer than in ulcer. General peritonitis may occur without perforation.

Carcinoma may extend by continuous growths into surrounding parts. It may also lead to metastases or secondary deposits. The lymphatic glands near the stomach, also the liver, the peritoneum, the pancreas, and the lungs, are affected in frequency in the order named. Secondary deposits in the liver are those most frequently detected during life.³ Metastases occur most fre-

¹ Thus Lebert states that in 9 per cent. of the cases cancer develops from simple ulcer (*Deutsches Archiv für klinische Medizin*, 1877, Bd. 19, S. 545).

² Perforation into the peritoneal cavity occurs, according to Brinton, in a little more than 4 per cent. of the cases; according to Lange, in a little more than 5 per cent.

³ In Welch's statistics (1574 cases) the lymphatic glands were the seat of metastases in 35 per cent., the liver in 30, the peritoneum or intestine in 23, the pancreas in 8, the pleura and lung in 6, and the spleen in 2 per cent. of the cases.

quently through the lymph-vessels, but they may also occur through the blood-current. An actual growth of carcinoma into the rootlets and main trunk of the portal vein has been observed. The secondary deposits generally conform in structure with the primary growth. It is worthy of note that large and abundant secondary deposits may attend small and insignificant tumors of the stomach which during life may have produced no symptoms, and after death may be overlooked on superficial examination. The blood in cases of cancer of the stomach may present the same alterations as in pernicious anæmia.

The SYMPTOMS which make up the clinical history of this affection are as follows: Impaired appetite, or anorexia, is generally more or less marked, but in some cases the desire for food is preserved. Pain may be more or less prominent, and the character of the pain may be lancinating. In many cases, however, the lancinating pain which attends cancer in other situations is either slight or wanting. A circumscribed gnawing pain may be incident to the ulcer occurring as secondary to the cancer. Tenderness over the epigastrium may or may not exist. Vomiting is a frequent symptom, but it occurs less frequently than in cases of simple ulcer, and at a later period after taking food. The vomiting, if the cancer be at the pylorus, may be due chiefly to obstruction at this orifice and consequent accumulation of gastric contents. Yeast-fungi, sarcinæ, and torulæ may be found in the vomited matters when these have undergone fermentation within the stomach. Blood is not infrequently found in the vomited matters, generally in small quantity and having the coffee-grounds appearance. With these symptoms referable to the stomach are associated progressive loss of weight and strength, anæmia, usually constipation, but occasionally diarrhœa, and in some cases jaundice. The last-named symptom points to the probable occurrence of secondary cancer affecting the liver.

As to the primary cause of cancer, we are without any positive information. It is probable that the cachexia is secondary to the development of the cancer. The cachexia may be explained partly by certain facts pertaining to cancer in general, and in part by the local injury which the growth inflicts upon an organ of such vital importance as the stomach. The general considerations are—the rapid growth of the tumor; its withdrawal in a short time from the circulation of a large quantity of nutriment employed only for its own noxious growth and for no useful purpose; its destruction of healthy and useful tissues; the production of metastases, which for their nutrition and growth, from their number and size, make even greater claims upon the organism than the primary tumor; and often the occurrence of exhausting hemorrhages. The local effects of the cancer of the stomach—loss of appetite, pain, vomiting, mechanical disturbance of the digestive functions, and chemical alterations in the gastric fluids—are often in themselves sufficient to explain an extreme degree of cachexia. While these general and local effects suffice to explain the cachexia in most cases of carcinoma of the stomach, there are a small number of cases in which they do not seem to be operative, and in which it seems necessary to assume the entrance into the blood of some virus produced in the tumor.

The liability to cancer of the stomach is slight before the age of forty. Three-fourths of all cases occur between forty and seventy years of age; the largest number being between fifty and sixty. Men are somewhat more frequently affected than women, but the disproportion is not great.¹ Heredity is a well-established element in the causation of cancer of the stomach as of cancer elsewhere.

Cancer of the stomach is to be discriminated from merely functional disorder or dyspepsia, chronic gastritis, and gastric ulcer. In merely functional

¹ In 2214 cases of gastric cancer there was a ratio of 5 males to 4 females (Welch).

disorder, pain and vomiting are symptoms rarely as prominent as they are generally in cancer. The ailments in dyspepsia are seldom so protracted; they do not lead to the same amount of emaciation, feebleness, and pallor; hæmatemesis is wanting. The same is true of chronic gastritis. Persistent disturbance of digestion, especially if accompanied by pain and vomiting, leading to considerable loss in weight, diminution of strength, and anæmia in a person between forty and seventy, should always excite suspicion of cancer. Cases of gastralgia lack all the diagnostic features of cancer except pain. Gastric ulcer is liable to be confounded with cancer, and in view of the great difference as regards prognosis it is desirable to discriminate between these affections. They present certain points in contrast as regards the symptoms. In cancer the appetite is more impaired than in ulcer. Vomiting is more uniformly present in ulcer; it occurs earlier after the ingestion of food, and in general is evidently due to the irritation caused by the presence of food. In cancer it is present in only a certain proportion of cases; it does not follow so soon after taking food, and is frequently due to the mechanical distension of the stomach owing to the pyloric obstruction. Hemorrhage is more constant and more profuse in ulcer. If the patient be a young girl, the chances are much in favor of ulcer. The duration of the local symptoms is of importance in this differential diagnosis. If the symptoms have existed for a long period, the chances are in favor of ulcer rather than of cancer. Age is to be considered in the diagnosis, cancer occurring rarely before forty. Enlargement of lymphatic glands above the clavicles accompanies cancer in some cases and has some weight in the diagnosis.

Considerable importance has been attached to the complexion which has been supposed to denote the cancerous cachexia—namely, pallor with a faint tint of yellow or green, the conjunctiva remaining unaffected. It has been called a waxy complexion. This is sometimes well marked in cases of cancer, but it is by no means always present, nor is it pathognomonic when marked. If members of the family have had cancer, this fact is entitled to some weight in the diagnosis. So also is the coexistence of cancer in some other situation.

Considerable interest attaches to the discovery by Von den Velden that hydrochloric acid is habitually absent from the stomach in cases of gastric dilatation due to cancer. [The claim that hydrochloric acid in a free state is, as a rule, persistently absent from the gastric secretions in cases of cancer of the stomach has been abundantly verified. The greatest amount of clinical evidence in support of this proposition has been furnished by Riegel. This observer studied 16 cases of cancer of the stomach,¹ in 5 of which the diagnosis was confirmed by an autopsy. In these 5 cases he made 154 analyses of the contents of the stomach, with a digestive test and quantitative estimate of the amount of acid present. In none of these numerous analyses was free HCl found, and in no instance did the filtrate of the stomach-contents possess the power of digesting albumen. In 8 of the remaining 11 cases 120 analyses failed to find either HCl or digestive power in the gastric juice. In the following 3 there were found at first a very weak HCl reaction and feeble digestive power. They were therefore regarded as cases of incipient carcinoma. Later, free acid was no longer found. From these observations Riegel concludes that in the gastric juice of a cancerous stomach, as a rule, both free HCl and digestive power are absent, and that, on the other hand, if in any case free HCl and normal digestive power are present carcinoma may be excluded, in spite of the usual symptoms of that disease.]

The above conclusions of Riegel express the opinion of all authorities on gastric cancer so far as the presence or absence of HCl is concerned. With

¹ *Zeitschrift für klin. Med.*, Bd. xii.

or explanation, however, they are misleading, inasmuch as they : the diagnostic importance of the acidity of the gastric juice. adoubtedly absent, as a rule, from the secretion of a cancerous out the same is true of other affections, such as atrophy of the cosa, amyloid degeneration, chronic catarrh, simple dilatation, and mpaired innervation. Anacidity, therefore, instead of being, as at sed, pathognomonic of cancer, must be relegated to the position ble corroborative sign of that disease.—H.]

cases of cancer there are few or no symptoms denoting any serious p to a short time before death. Like gastric ulcer, it is sometimes y latent, the patient seeming to suffer only from moderate or slight ailments, the appetite remaining unimpaired, the strength not fail- ie aspect indicating health. Several cases illustrative of this fact i under my observation. In these latent cases, and also when the

diagnosis relates to ulcer and chronic gastritis, great importance the discovery or otherwise of an abdominal tumor in the site of h. Exclusive of the cases in which the cardiac orifice is the seat er, a tumor is discoverable by physical examination in the majority

According to Brinton, it exists in 80 per cent. of all cases of can- tumor is situated generally between the false ribs and the umbil- le to the right of the median line. It may be movable or fixed ; e frequently the latter. If movable, it will be likely to change n accordingly as the stomach is distended or empty. The tumor ize from a pigeon's egg to the size of the closed hand. The weight or may cause it to fall below the epigastrium, and it may descend the symphysis pubis. It is usually resisting and the surface is r nodulated.

sence of a tumor, if ascertained to be seated in the stomach, renders is almost positive ; but it is not always easy to decide positively mtor is seated in the stomach. A cancerous tumor may simulate f the abdominal aorta. The characters of an aneurismal tumor are ulation, thrill, and murmur. A cancerous tumor may present, in a s marked degree, the same characters. It may present not only a double murmur. How are the two to be distinguished from each i aneurismal tumor has usually a smooth outline and may be dimin- ressure ; the pulsation is felt laterally as well as on its anterior sur- change of position of the patient, as placing him on his hands and pulsation is not materially affected, whereas if the tumor be not its pressure on the artery is taken off and the pulsation may be ease. But aneurismal tumors do not always pulsate, and both thrill ur may be wanting. Under these circumstances in this differential eliance must be had upon the diagnostic points relating to the l symptoms. These are, of course, always to be carefully consid- er tumors, from their situation, are liable to be confounded with the stomach—namely, tumors connected with the left lobe of the rith the pancreas, fecal tumors, etc. The distinctive characters of be considered in other connections. A point of distinction, as con- h tumors seated in the liver, is that the latter are depressed in an p inspiration, whereas the descent of the diaphragm does not affect on if the tumor be seated in the stomach. Moreover, percussion largement of the left lobe of the liver gives flatness, whereas a resonance is elicited usually over a gastric tumor. There is a mistake the normal pancreas for a tumor ; and owing to different distension of the stomach the tumor may be felt at some times ; other times.

Cancerous affection of the cardiac orifice, leading to stenosis, gives rise to symptoms quite different from those which accompany cancer of the stomach elsewhere situated. Food accumulates in the lower part of the œsophagus and is regurgitated directly after deglutition. The obstruction, if considerable, interferes with vomiting as well as with the ingestion of food. The food is regurgitated without change, and is devoid of the taste and odor of the gastric fluids. The patient is unable to take solid food, and is compelled to take liquids slowly and in small mouthfuls. In these cases a tumor is not discoverable. The symptoms are the same as in cases of stricture at the lower portion of the œsophagus from other than cancerous disease, and the differential diagnosis cannot always be made with positiveness. Spasmodic stricture of the œsophagus may simulate contraction from either cancer or some other organic affection. The passage of a probang into the stomach will enable the practitioner to exclude the latter. Adhering to the probang or sound passed into the cardiac orifice, may be cancerous particles, which establish the diagnosis.

A microscopical examination of the matters vomited in cases of suspected cancer may lead to the discovery of cancer elements. This test is available only at an advanced period of the disease, and then only in a very small proportion of cases.

The PROGNOSIS in cases of cancer of the stomach is as unfavorable as possible. If a cure be within the range of possibility, the probabilities are so vastly against it that we are not warranted in entertaining the least expectation of such a result in any individual case. A fatal termination is merely a question of time. Statistics show the average duration to be about a year from the date of the first gastric symptoms. The maximum duration is about three years, and the shortest period is a month. Death occurs by slow asthenia, except in rare instances when it follows profuse hemorrhage or perforation of the stomach. Œdema of the lower limbs and ascites occur in some cases. The former may be caused by thrombosis of the femoral veins; the latter may be produced by pressure upon the portal vein of a cancerous nodule connected with the liver or the formation of a thrombus within the vein.

The TREATMENT has reference only to the prolongation of life and the palliation of symptoms. A diet bland and nutritious, consisting of the articles of food which experimental trials in each case show to be best borne, taken in quantities and at intervals to be determined also by trial; remedies to relieve pain and quiet the irritability of the stomach; avoidance of cathartics and any measures which impair the vital powers,—these are the points to be kept in view in the management of this distressing and hopeless affection. Nourishment by means of rectal alimentation in cancer of the stomach involving pyloric obstruction prevents pain and vomiting resulting from the accumulation of ingesta and the chemical changes incidental thereto. It may be resorted to as supplementary to a limited quantity of food taken into the stomach. Withdrawal from time to time of the accumulated contents of the stomach by means of the pump or siphon, in the manner to be described in connection with Dilatation of the Stomach, has been found to afford marked relief. In cases of cancer causing obstruction of the cardiac orifice the sensation of hunger is removed and life prolonged by resorting to rectal alimentation. These desirable results were manifested in a case under my observation. Buttermilk is sometimes better tolerated in cases of cancer than any other article of diet. [In most cases starchy foods—such as arrow-root, sag and tapioca—and the liquid preparations of beef are best digested. To these may be added a small quantity of brandy, which imparts an agreeable flavor to most of the preparations of starch. Gelatin may be given a trial, and

although practically devoid of nutriment, is a valuable addition to the dietary on account of the albumen-sparing property which it undoubtedly possesses. In other words, an individual who consumes a small amount of gelatin can support life and maintain his nutrition with less albuminous food than can another who eats no gelatin. Another valuable property of gelatin in cases of carcinoma is that it is decidedly laxative. It is, when properly prepared and flavored, a most palatable article of food, and may be prescribed in the form of peptonized milk-jelly, which is composed of peptonized milk to which, while hot, a certain amount of gelatin is added. It is then sweetened, flavored with orange, lemon, wine, brandy, or rum, and eaten cold.—H.] Cases have been reported in which the condurango appeared to have a beneficial effect.

Since the preceding edition of this work there have been more than 40 published resections of cancer of the pylorus. Of these, about 30 have died from the immediate effects of the operation. In no case does life seem to have been prolonged more than two years after the operation. Only a very small proportion of the cases of gastric cancer can be considered as suitable for operation. The possibility of successful surgical interference renders it very important to make an early diagnosis. In the hands of a skilful surgeon an exploratory laparotomy is attended with little or no danger.

Dilatation of the Stomach—Gastrectasia.

Since Kussmaul's publication,¹ in 1869, concerning the treatment of dilatation of the stomach by means of the stomach-pump increased attention has been devoted to the etiology, symptomatology, and treatment of this affection. As the normal dimensions of the stomach vary in different individuals within wide limits, it is manifestly impossible to give an exact anatomical definition of this disease. While well-marked examples cannot be mistaken in post-mortem examination, it is often impossible to recognize the lesser grades of this disease. During life certain characteristic disturbances of the physiological functions of the stomach are of great importance in reaching a diagnosis—sometimes of greater importance than the anatomical investigation.

When dilatation of the stomach is excessive the organ may occupy the greater part of the abdominal cavity, and may even descend into the pelvis. In less extreme cases the lowest part of the stomach lies somewhere between the umbilicus and the symphysis pubis. By increased weight the whole organ is generally dragged downward, especially the pyloric portion when it is movable, so that the position of the stomach is more nearly vertical than normal. When dilatation is due to stenosis of the pylorus the muscular coat is almost invariably hypertrophied. In the so-called atonic dilatation to be described presently the muscularis may be of normal or of reduced thickness. In one case fatty and colloid degeneration of the muscular fibres was found (Kussmaul and Maier). The mucous membrane is sometimes thickened and sometimes thinned. It is readily understood that neighboring organs may be more or less displaced by a widely-distended stomach.

It is important to know that the stomach may be situated abnormally low in the abdomen without being dilated. Thus if, during life, the lower part of the stomach be found a hand's breadth below the umbilicus, it does not necessarily follow that it is dilated. The so-called vertical position (*situs verticalis*) of the stomach is a not infrequent malposition which simulates dilatation. In this condition the pyloric orifice is lower than normal, and it may be in nearly a vertical line with the cardia. The position may be a preservation of the foetal state, or it may be acquired as a result of pressure (in women especially by

¹ *Deutsches Archiv f. klin. Med.*, Bd. 6, p. 455.

tight lacing). As pointed out by Kussmaul, the greater curvature may occupy an abnormally low position in consequence of the so-called loop shape (Schlingen-form) of the stomach. In this state the pylorus is nearer the cardia than normal, and the lesser curvature is abnormally sharp.

Kussmaul distinguishes two forms of dilatation of the stomach, the hypertrophic and the atonic.¹ In the former the muscular coat is hypertrophied, and the cause in the great majority of cases is obstruction at or near the pyloric orifice. In the atonic form the muscular coat is relaxed, and after death it is found but little if at all hypertrophied, and it may be atrophied. Hypertrophic dilatation he compares, not inappropriately, to eccentric hypertrophy of the heart.

The causes of dilatation relate, in the first place, to mechanical obstacles to the passage of the contents of the stomach into the intestine. The obstacles may be various. They may be seated in the upper part of the duodenum as well as in the stomach. The most frequent and important are cancer and the cicatrices resulting from old ulcers. Other causes of organic stenosis of the pylorus are—tumors of neighboring organs, causing external pressure, particularly cancer of the liver and of the pancreas; the contraction of cicatricial tissue resulting from perigastritis and the inflammation of connective tissue near the stomach; hypertrophic stenosis (see p. 347); the pressure upon the duodenum of a wandering right kidney; and, as rarities, fibroma, lipoma, glandular and cystic polypi of the pylorus. A very rare condition is congenital stenosis of the pylorus.² Dilatation has been referred to traction upon the stomach produced by large scrotal hernias. According to Kussmaul, it may be referable to spastic stenosis of the pylorus. The sphincter pylori may be thrown into spasmodic contraction by painful erosions, ulcers, and inflammations in its neighborhood. Destruction of a part of the muscular coat near the pylorus is evidently an obstacle to the propulsion of food through this orifice, and so may lead to dilatation. In this way ulcers and cancers which destroy the muscularis may produce dilatation even when they do not obstruct the lumen of the stomach. It has already been mentioned that cirrhosis of the stomach, which is usually attended by contraction, may exceptionally be accompanied by dilatation.

Atonic dilatation may be due to weakness of the muscular tone of the stomach from imperfect nutrition in cases of anæmia, chlorosis, exhausting acute and chronic diseases, or amyloid degeneration of the gastric arteries. Important causes of dilatation of the stomach are chronic gastritis and dyspepsia, especially when attended by stagnation and fermentation of the gastric contents. Individuals of sedentary habits who eat and drink a great deal are liable to dilatation. The polyphagia which attends diabetes thus becomes a cause of dilatation. The dilatation which results from organic stenosis of the pylorus reaches a more extreme degree than that from other causes, and is accompanied by a greater hypertrophy of the muscular tunic.

Vomiting occurs almost without exception when dilatation is due to pyloric obstruction; and in other cases it is a frequent but not a constant symptom. The characteristic features as regards this symptom are the occurrence of the vomiting after periods varying from a day to several days, the large quantity of the matters vomited, amounting sometimes to several quarts, and the presence of undigested aliment which had been taken the previous day or several days previously. The matters vomited are almost invariably acid, and frequently they are in a condition of fermentation, as indicated by a

¹ Kussmaul, "Die peristaltische Unruhe des Magens," *Volkmann's Sammlung klinischer Vorträge*, Leipzig, 1880.

² Landerer, *Ueber angeborene Stenose des Pylorus*, Tübingen, 1879.

froth containing gas, sometimes inflammable, in the upper layers. *Sarcinae*, the yeast-fungus, bacteria, and crystals of fatty acids are often found. Acetic, lactic, butyric, and other organic acids are usually present. Von den Velden has discovered an interesting fact in regard to the presence of hydrochloric acid, the normal acid of the gastric juice. He failed to find this acid in any case of dilatation due to cancer of the stomach. In dilatation from other causes it was often, but not invariably, present. According to this author, if hydrochloric acid be repeatedly detected in the contents of the stomach obtained by means of the stomach-pump, obstruction from cancer may be excluded. If this acid be persistently absent, no positive conclusions can be drawn. Bile is not often found in the matters vomited or withdrawn by the stomach-pump if the dilatation be due to stenosis of the pyloric orifice.

The feature pertaining to the contents of the stomach which appears to be most diagnostic of dilatation is their retention for a day or for several days within this organ. This may be ascertained by washing out the stomach in the morning before food has been taken. In healthy persons the stomach does not contain in the morning any of the ingesta of the preceding day. The ingesta may remain overnight in cases of temporary indigestion, but if they are habitually present in the morning, it is certain that the power of the stomach to propel its contents into the duodenum is wanting. This condition leads to dilatation. It is called by Rosenbach insufficiency of the stomach, and of course it may exist for a time before dilatation ensues.

Dilatation of the stomach may occasion an abnormal prominence of the abdomen, especially marked at the epigastrium and extending more or less below the umbilicus. The projecting tumor yields at the upper part a tympanic resonance on percussion having the characteristic gastric quality of sound. At the lower portion, if the stomach contain ingesta, there is flatness on percussion, and the relative situation of the flatness and tympanic resonance changes when the position of the patient is changed from the vertical to the recumbent. On succussion a splashing sound is produced analogous to that in pneumo-hydrothorax. With the ear or stethoscope placed over the stomach, metallic tinkling may be heard when the patient swallows liquid. Sometimes a sizzling sound is produced by bubbles of gas generated by fermentation. These auscultatory signs, however, are not distinctive of dilatation. They may be caused by the presence of air and liquid in a stomach more or less distended, but not dilated. If the abdominal walls be thin, the form of the stomach may be apparent and its undulatory movements visible. According to Kussmaul, these peristaltic undulations are characterized by their intensity, their long duration, and by coming on speedily after meals. They may give rise to disagreeable sensations, whereas in health persons are unconscious of the peristole of the stomach. The enlargement of the stomach varies at different times according to the variations in the quantity of ingesta and gas. A sense of fluctuation may be perceived by the touch when the stomach contains considerable liquid.

With the object of ascertaining the amount of dilatation by the eye and by percussion the method of generating gas within the stomach, as first proposed by Frerichs, may be resorted to. The quantity of effervescing powder required to bring out distinctly the contour of the organ varies in different persons according to its capacity, the tension of the walls of both the stomach and the abdomen, the reflex susceptibility to vomiting, etc. From 20 to 30 grains of bicarbonate of soda and from 15 to 20 grains of tartaric acid may be at first introduced. The soda is to be given in a little lukewarm water and followed by the acid. Some persons with relaxed, dilated stomachs require 2

or 2½ drachms of soda and a corresponding quantity of acid.¹ The amount of dilatation may also be demonstrated by means of a stomach-sound, the length which is introduced being ascertained, and the extremity can sometimes be felt by the hand applied over the abdomen.

It is important to know that a person may be found to have an unusually capacious stomach, but if it do its work well—that is, if it be sufficient in the sense in which this term is used by Rosenbach—and is empty in the morning there is no propriety in considering the large size of the organ as a morbid condition, any more than a similar condition of the bladder. On the other hand, the signs may not denote much enlargement; but if the organ be insufficient, its muscular power being inadequate to propel the contents during the night into the intestine, either dilatation exists or a condition leading thereto. Since attention has been directed to dilatation of the stomach more than heretofore, it has probably not infrequently been diagnosed on insufficient grounds. No organ in the body varies in volume more widely within the range of health than the stomach, and an unusually large volume is not to be considered as dilatation unless the symptoms denote habitual undue detention of the ingesta.

In cases of dilatation the quantity of urine is often diminished and its reaction is alkaline. The bowels are constipated. The body wastes from innutrition. The symptoms of cancer of the stomach when the pylorus is obstructed are referable in a great part to the dilatation which ensues.

Paracentesis has been practised in a case of enormously dilated stomach under the belief that the affection was hydro-peritoneum. Physical examination of the abdomen, in addition to the symptoms characteristic of dilatation, should enable the practitioner to avoid this error. In hydro-peritoneum the enlargement is not uniform, but is greatest at the lower part of the abdomen, the reverse being true of dilatation of the stomach. In hydro-peritoneum the enlargement is proportionate anteriorly and laterally; in dilatation of the stomach the anterior projection is greater than the lateral. In hydro-peritoneum flatness on percussion exists at the lower part of the abdomen; in dilatation of the stomach intestinal tympanitic resonance will be likely to be found below the space which yields flatness—namely, in the hypogastric and iliac regions. The variation in the enlargement and its disappearance after complete vomiting or the use of the stomach-pump suffice for the diagnosis.

If not dependent on pyloric stenosis a considerable degree of dilatation may not give rise to notable inconvenience; but if the dilatation be great, nutrition suffers in consequence of the non-absorption of the accumulated ingesta. Rupture may occur if the walls be attenuated. A fatal termination, however, irrespective of carcinoma or other diseases which occasion obstruction, is rare.

[In the TREATMENT of gastrectasia there are two principal indications, the one general, the other local. The first is the nourishment of the patient; the second, the relief of the distended stomach.

The diet should be as dry as possible, for fluids are not only almost useless for nutritive purposes, on account of the difficulty with which they are absorbed, but are of positive injury by increasing the distention already present. No better proof of the hindrances to absorption can be adduced than the fact that the patient is often suffering from thirst when his stomach is distended with

¹ Ebstein has described under the name insufficiency of the pyloric valve (incontinentia pylori) a condition in which the gas thus generated is not retained in the stomach, but rapidly escapes into the intestines through the pyloric orifice. (Vide "Ueber die Nichtschlussfähigkeit des Pylorus," *Volkmann's Sammlung klinischer Vorträge*, No. 155, 1878.)

fluid. These remarks with reference to the ingestion of fluids apply to those periods of the disease when the stomach already contains an excessive amount of liquid. After the organ has been thoroughly emptied of its contents a certain amount of fluid may be administered, and preferably in the form of peptonized milk. The main staple of the diet should be meat, either peptonized (beef-peptones) or finely scraped and broiled (Hamburg steak). The digestion of this animal food should be assisted by the frequent administration of dilute hydrochloric acid—15 to 20 drops in a tablespoonful of water every three hours. All starchy foods, sugar, and beer—in a word, all substances which ferment readily—should be prohibited. With a moderate quantity of peptonized milk, a considerable amount of scraped broiled beef, and rectal enemata if necessary the nutrition will be sufficiently provided for.

To fulfil the second indication the only advisable procedure is lavage. This is accomplished by introducing into the stomach a rubber tube to the outer extremity of which a funnel is attached. Through this, water is poured until the stomach is distended, when the funnel is depressed below the level of the umbilicus and the water rushes out in obedience to well-known hydrostatic laws, the apparatus being neither more nor less than a siphon. The manœuvre of filling and emptying the stomach may be repeated several times at one sitting—in fact, it should be continued until the water returns perfectly clear. A great deal of tact and patience are required to bring the first lavage to a successful conclusion, and the operation should never be undertaken without the hearty co-operation of the patient. The relief which follows it is, however, so great that he will surely demand its repetition, and in many cases there is difficulty in dissuading him from abusing it. Lavage should not be employed until at least six hours have elapsed from the time of eating, and, on the whole, it is safest to practise it in the early hours, before breakfast. If performed too soon after meals, it may deprive the system of valuable nutriment.

After thoroughly washing out the stomach with water at or near the temperature of the body it may be finally cleansed with an antiseptic solution, such as salicylic acid, 3 to 5 *pro mille*, or borax, 2 to 4 per cent. These harmless substances are quite efficacious, although benzoic acid, naphthalin, potassium permanganate, and resorcin are also recommended by various authorities. The latter substance is unsafe except in very weak solution, such as half of 1 per cent.

The good effects of a thorough washing out of the stomach are immediate. The aspect of the patient becomes cheerful; pyrosis and eructations cease; the bowels become more regular; the urine increases in quantity and loses its alkaline reaction; and the bodily weight increases, sometimes even in cases where the dilatation has cancerous obstruction for its cause. Massage and electricity are excellent adjuvants to lavage. It was at one time doubted whether electricity applied to the abdominal walls could induce contractions of the stomach, but recent researches of Ewald and Sievers have demonstrated that the exit of the gastric contents is hastened by the energetic application of faradization to the abdomen. The most rational employment of electricity in gastrectasia consists in introducing a properly-constructed electrode into the stomach while its fellow is placed on the abdomen or in the rectum. Before introducing the electrode the patient should be directed to drink a glass or two of water.

Strychnia is a remedy of undoubted service in cases of gastrectasia, especially in the atonic forms of the disease. It may be given by the mouth in doses of $\frac{1}{30}$ of a grain thrice daily, or hypodermically if there be any reason to suspect that it is not absorbed. In the latter mode of employment the initial dose should not exceed $\frac{1}{30}$ of a grain.

Cathartics are also decidedly beneficial, not only on account of their mechanical effect in unloading the bowels, but also because of the intimate peristaltic relation between the stomach and intestines. They are most efficacious when administered immediately after washing out the stomach at which time a solution of Carlsbad salt may be poured in through the stomach-tube before its withdrawal. Other useful purgatives are colocynth, rhubarb, scammony, and aloes. The last mentioned may be given hypodermically in the form of the extract known as aloin.

Prophylaxis.—Although we possess no certain means of preventing the obstructive forms of dilatation, such as those dependent upon pyloric cancer, the cicatrices of ulcers, and the pressure of tumors of neighboring organs, we certainly have it in our power to reduce the number of cases of the purely atonic variety. With this end in view the greatest care should be taken to avoid distention of the stomach with fluid in patients recovering from febrile affections, and in the anæmic and debilitated generally. A certain number of such individuals are placed upon an exclusive milk diet, and necessarily consume large quantities of fluid. To avoid the disastrous effects of dilatation they should be instructed to take their milk in small amounts at short intervals, while at the same time their bowels are kept regular. In addition, it is a wise precaution to keep such patients upon the daily use of strychnia so long as their debility continues, and to apply the faradic current occasionally to the abdominal muscles.—H.]

Degeneration of the Gastric Tubules—Atrophy of the Stomach.

Together with the liver, kidneys, and heart, the stomach is a frequent seat of *parenchymatous degeneration* or *cloudy swelling*. In this condition the mucous membrane is somewhat swollen, and may be either congested or pale. The microscope shows the glandular cells to be swollen and filled with albuminous granules, which, at least in great part, dissolve in acetic acid. The contours of the cells may be so obscured that the tubules seem to be filled with a granular mass. This change, when of much intensity, frequently leads to *fatty degeneration*. The cells now contain fatty molecules which refract the light more than the albuminous granules, and are not soluble in acetic acid. In extreme degrees of this degeneration, such as may occur in phosphorus-poisoning, the cells are more or less disintegrated and their places occupied by a fatty and albuminous detritus. The most frequent and important causes of parenchymatous degeneration are the febrile and infectious diseases, of which may be specially mentioned typhus and typhoid fevers, smallpox, septicæmia, puerperal fever, and yellow fever. Phosphorus-poisoning has been mentioned as a cause of the more extreme grades leading to fatty degeneration. Poisoning by arsenic, mercury, or the mineral acids is said to produce similar changes. It cannot be doubted that these alterations in the peptic cells impair the secretion of the gastric juice. It is reasonable to refer to them many of the disturbances in digestion which characterize the conditions named. Parenchymatous degeneration in the stomach, as elsewhere, is a condition from which recovery readily takes place when its causes are removed.

While treating of the different forms of gastritis, reference was made to changes of the tubules, mostly of a degenerative character, which occur in inflammatory states. Parenchymatous and fatty degenerations and atrophy of the tubules were the most important of these alterations. An interesting comparison is often drawn between the changes in the gastric mucous membrane in chronic inflammation and those in the kidney in chronic diffu-

ephritis. In both there are increase of the interstitial tissue, fatty degeneration of the glandular epithelium in certain places, atrophy of the tubules, with constriction of the tubules at certain points and cystic dilatation at others.

There is reason to believe that degenerative changes in the gastric mucous membrane occur independently of chronic inflammation and of the various causes of parenchymatous degeneration. *Atrophy of the stomach, atrophy or degeneration of the gastric mucous membrane or of the gastric tubules*, are names which have been employed to designate these changes. Alterations in the gastric glands have been studied especially by Handfield Jones, Wilson Fox, Habershon, Fenwick, and Henry and Osler. It is generally recognized that atrophic changes occur in the mucous membrane of the stomach, as in other organs, in chronic wasting diseases and in old age; but it is maintained by Fenwick and others that atrophy of the stomach occurs also as a primary morbid condition attended by grave symptoms; in other words, that it constitutes a disease by itself. So long ago as in 1860, in a published lecture on anæmia, I ventured the opinion that degeneration of the gastric tubules is the anatomical characteristic in certain cases now included under the name of pernicious anæmia. (See p. 311 *et seq.*)¹ In the third edition of this work (1868) I predicted that future investigations would disclose important facts pertaining to morbid conditions seated in the gastric tubules. In an essay published in 1871,² I endeavored to still further substantiate these views. My conclusions were based partly on deduction and partly on the anatomical studies of Jones, Fox, and Fenwick. My object was to show, from a clinical point of view, *first*, the existence of a well-defined class of cases characterized by anorexia, impaired digestion, progressive debility, anæmia, and death from inanition; and *second*, in view of these clinical characteristics, together with the absence of adequate lesions elsewhere, the probability that the essential disease is seated in the secretory glands of the alimentary canal. It is gratifying to be able to add that recent years have furnished several contributions to our knowledge of this still obscure subject. Fenwick, in a lecture on atrophy of the stomach in 1877,³ published four cases with autopsies showing atrophy of the gastric tubules without thickening of the walls and without diminution of the lumen of the stomach. The symptoms resembled closely those which have been described in the article on Pernicious Anæmia. Quincke, in an essay on pernicious anæmia,⁴ mentions a case in which the gastric symptoms were even more marked than is usual in pernicious anæmia, and in which after death the gastric mucous membrane was found to be thin and pale, the glands being few and far apart. He suggests that the atrophy of the gastric mucous membrane may have been the starting-point of the disease. Brabazon in 1878⁵ reported a case of general atrophy of the stomach with absence of organic disease. The symptoms during life were anorexia and extreme anæmia. The walls of the stomach were found to be atrophied, but, unfortunately, no microscopical examination was made. In 1879, Nothnagel⁶ published a case of cirrhotic contraction of the stomach attended by disappearance of the gastric glands in all parts except the pyloric region. The microscopical examination was made by W. Müller. The clinical history of this case was in all respects that of pernicious anæmia, and this was the diagnosis during life. Nothnagel does not

hesitate to refer these symptoms to the atrophy of the gastric tubules. As he remarks, atrophy of the gastric glands appears under two conditions, the one with and the other without thickening of the walls of the stomach. The former condition corresponds to cirrhosis of the stomach, the latter to simple atrophy. It is the latter form to which Fenwick has called especial attention. In some of the reported cases an increase of the interstitial tissue of the mucous membrane has been observed, but whether it be primary or secondary is uncertain. Even if the interstitial change prove to be primary, there is no propriety, as Nothnagel justly says, in considering the process as an ordinary chronic catarrhal gastritis. A case of fatal atrophy, the history being that of pernicious anæmia, has been recently reported by Thorowgood, and a similar case has been carefully studied and reported by Henry and Osler.¹

The SYMPTOMS which have been observed in cases of atrophy of the gastric tubules are those of severe anæmia. The digestive symptoms are—loss of appetite, vomiting (usually but not always), distress after eating, and eructations. These are symptoms in cases of pernicious anæmia. It is desirable, as Nothnagel suggests, to pay special attention to the condition of the stomach in death from pernicious anæmia. The pathological conditions are probably not the same in all cases of this grave form of anæmia. That a certain proportion of the cases are referable to atrophy of the gastric tubules may reasonably be inferred from cases already published. From a clinical standpoint it is important to take cognizance also of atrophy of the glands of the stomach as a secondary change in various affections of this organ, especially in chronic inflammation and in cancer. It is to be expected that in the future greater attention will be directed to the condition of these important glands in disease, and that valuable contributions will thereby be made to our knowledge of this recently-opened field of research.

Waxy degeneration of the walls of the stomach is not a very infrequent condition in cases in which this degeneration is widely extended. As a rule, the metamorphosis is more marked in the small and large intestine than in the stomach. All the coats of the stomach may be involved, but generally the change is greatest in the muscularis mucosæ and the mucous membrane. Here, as elsewhere, the waxy material appears first in the walls of the small arteries and about the capillaries, and it may be confined to these structures. The change may, however, extend to the surrounding tissues. In the majority of cases the epithelial cells of the tubules do not undergo the waxy metamorphosis. According to Kyber, amyloid degeneration of the stomach is generally accompanied by chronic inflammatory changes and pigmentation. Extensive amyloid degeneration may so impair the nutrition of the gastric mucous membrane as to favor the development of round ulcer. Although, according to Kühne, the amyloid material outside of the body is extremely resistant to the action of the gastric juice, it would appear from the studies of Kyber that this substance in the living body may be digested by the gastric juice. Amyloid degeneration is generally an accompaniment of severe wasting disease. That the functions of the stomach are impaired by this metamorphosis is in the highest degree probable, but we are without positive information on this point.

CHAPTER IV.

FUNCTIONAL DISORDERS, OR NEUROSES OF THE STOMACH.

Introductory Remarks.—Motor Neuroses (Nervous Vomiting; Peristaltic Unrest; Nervous Eructation; Rumination; Incontinence of the Pylorus; Atony).—Sensory Neuroses (Gastralgia; Polyphagia, Malacia and Pica, Polydipsia, and Dipsomania).—Secretory Neuroses (Hyperacidity and Hypersecretion).—Nervous Dyspepsia.—Gastrorrhagia.—Inanition.

[INTRODUCTORY REMARKS.]

BEFORE beginning the study of the functional diseases of the stomach it is necessary to have some knowledge of the methods by which they are investigated, especially as, within the last few years, great advancement has been made in this department. Formerly the diagnostic procedures in gastric disease were limited to inspection, palpation, percussion, and the inspection, gross and minute, of vomited matters, but the chief reliance was on the anamnesis and other subjective evidence. The primary object of diagnosis was then, as now, to distinguish between functional and organic disease, and if the latter could be excluded, the affection was decided to be "dyspepsia." The term "dyspepsia" is rapidly becoming obsolete so far as its employment in scientific writings is concerned. It was a most serviceable cloak for ignorance, but has been worn threadbare and is about to be discarded. We have no more scientific right to speak or write of dyspepsia as though it were a distinct disease than we have to be satisfied with the diagnosis of "jaundice" or "dropsy."

Our present knowledge of gastric diseases is almost entirely due to the use of the stomach-tube, which was first employed for diagnostic purposes by Leube in 1871. The instrument first used was hard and stiff, and was passed into the stomach with little or no active co-operation on the part of the patient; or if a soft-rubber tube was used, it was thought necessary to have it stiffened with a stylet of whalebone. By degrees it was ascertained that, unless there existed a stricture of the œsophagus, a soft-rubber tube open at the end and at the sides just above the end could be introduced with very little discomfort to the patient, who, besides, was able to give very valuable assistance in the operation by movements of deglutition. In fact, after a little practice the patient can swallow the tube much more readily than the physician can insert it. It is unnecessary to lubricate the tube with oil or vaselin or anything of the sort, for the saliva and mucus of the buccal cavity are sufficient for this purpose. The instrument is dipped in warm water, its extremity passed rapidly and deftly into the pharynx, and the patient directed to swallow it. In most cases success will attend the first efforts, but with hysterical patients it will not be achieved without considerable firmness and perseverance on the part of the physician.

The object of introducing the tube is to obtain a sample of the contents of the stomach with a view to its chemical analysis, and therefore the time at which the operation is performed is a matter of great importance. During the intervals of digestion the stomach contains a very little fluid which certainly does not deserve the name of gastric juice. It is really nothing more than a feebly acid mucus, from an examination of which no legitimate deductions with reference to the digestive power of the stomach can be made. Before introducing the tube the stomach must be stimulated to

secretion, and for this purpose various means have been resorted to. Leube's method is to inject through the tube, previously introduced, 100 cc. of ice-water, followed ten minutes later by three times that amount of water of ordinary temperature. The liquid, after a short stay in the stomach, is withdrawn, its chemical reactions examined, and its digestive power tested. This method has been criticized on the ground that a genuine gastric juice is only secreted in response to stimulation by a substance which it is capable of digesting. This objection is well founded, and therefore several so-called "test-meals" have been proposed by various investigators. Among these may be mentioned the hard-boiled egg used by Jaworski to obtain a sample of gastric juice, the meal composed of soup, beefsteak, and bread prescribed by Riegel, and the "test-breakfast" of Ewald. The latter is composed of a roll weighing about 35 grammes and a cup (about 250 ccm.) of weak tea. Discrepancies in the results of various investigators have been due to the fact that the gastric juice has been obtained by stimulating the stomach with food varying in amount and quality. Food is the natural stimulant of the gastric secretion, but the amount and quality of the latter and the period at which digestion is most active depend upon the amount and kind of food administered. It is therefore of great importance for experimenters upon digestion to agree upon the ingredients and amount of the so-called test-meal—in other words, to carry out their investigations upon a uniform plan. For several reasons the test-breakfast (*Probefrühstück*) of Ewald is better than any other. In the first place, the digestion of such a meal is at its height in one hour after eating, instead of from four to six, as after a meal composed of soup, bread, and meat. Secondly, if vomiting occurs during or after the introduction of the tube, the matter ejected is comparatively inoffensive both to physician and patient. These are sufficient grounds on which to base a decided preference for the test-meal of Ewald.

The tube having entered the stomach, the question is how to obtain the gastric juice. This may be accomplished either by suction or pressure. By means of a syringe or a rubber ball attached to its upper end the requisite amount (a few cubic centimetres) of fluid may be drawn into the tube. This is the simplest method, and if carefully performed the risk of injuring the gastric mucous membrane, upon which great stress has been laid, is entirely avoided. Ewald prefers what he calls the expression method, which simply means that the patient at the word of command contracts his abdominal muscles so as to force the contents of the stomach into the end of the tube. The latter should of course be compressed during its withdrawal, to prevent the fluid escaping by atmospheric pressure. This method, like all diagnostic procedures requiring the co-operation of the patient, will frequently fail, so that the operator should always be provided with some kind of suction apparatus—syringe, rubber ball, etc.

The requisite amount of fluid having been obtained, it is filtered and examined with reference to its chemical reaction and digestive power.

First, as to its chemical reaction. The contents of the stomach are always acid, but the object of the examination we are now considering is chiefly to determine the presence or absence of the true digestive acid, which is now universally agreed to be hydrochloric.

Numerous substances have been employed as tests of the presence of hydrochloric acid in the gastric juice, but, as in testing urine for sugar or albumin, so here, it is better to be thoroughly familiar with two or three of the best tests than superficially acquainted with a dozen. One of those most frequently employed is the methyl-violet test. It is thus applied: Into each of two tubes is poured a small quantity (50 cc.) of distilled water followed by two drops of a two per cent. solution of methyl-violet. Into

one of these tubes is now poured, drop by drop, the fluid, previously filtered, obtained from the stomach. To the other is added an equal quantity of pure water. If free hydrochloric acid is present in the gastric secretions, the fluid in the first tube will turn blue, while that in the latter will retain its violet hue. An objection to this test is that it is interfered with to a greater or less extent by albuminates and peptone, as well as by certain salts, especially phosphates and sodium chloride. The organic acids, lactic, butyric, and acetic, give the same reaction, but only when in a degree of concentration rarely present in the stomach. In the opinion of the writer, the best test is that devised by Günzburg of Frankford. It is known as the "phloroglucin-vanillin test," but, for the sake of brevity as well as in honor of its discoverer, should be called "Günzburg's test." It is composed of 2 grammes of phloroglucin and 1 gramme of Merck's vanillin in 30 grammes of absolute alcohol. The solution is of a yellowish-red color, but alters on exposure to light, and therefore when not in use should be kept in a box. If a drop of this solution be placed in a watch-glass and to it there be added a trace of concentrated hydrochloric acid, a bright-red color instantly appears and at the same time a separation of minute red crystals takes place. Concentrated organic acids, such as lactic and acetic, give no such reactions. The mineral acid to which the reaction is due must be of a certain degree of concentration. If too dilute, neither the color nor the crystals appear until some of the water is driven off by heat. The following is the technique for the application of this test to the examination of the stomach-contents: A few drops of the filtrate of the latter are mingled in a porcelain dish or watch-glass with the same quantity of the test-solution and carefully heated. If free hydrochloric acid is present to the amount of one-tenth of one per cent., the red crystals will form; when present in smaller quantity there will be no crystalline formation, but bright-red streaks will appear in the fluid.

It is often a matter of diagnostic importance to determine the presence or absence of lactic acid in the gastric secretions. For this purpose Uffelmann's test is invariably employed: To an aqueous solution of the chloride of iron, so weak as to be almost colorless, are added a few drops of the filtrate of the gastric secretions. If they contain but a trace of lactic acid, the mixture becomes of a canary-yellow color.

Acetic acid is detected when present in large quantity by its unmistakable odor. To demonstrate it chemically the filtered gastric secretions are shaken up with ether and evaporated. A part of the residue is then filtered, and to it is added a drop of a neutral solution of chloride of iron. If acetic acid is present a beautiful blue color appears.

For the demonstration of butyric acid the gastric contents are shaken up as before with ether and evaporated. A small fragment of chloride of lime is now added, and if butyric acid is present minute oily drops will appear upon the surface of the liquid. This is due to the fact that butyric acid is insoluble in saline solutions.

For other chemical tests of the gastric secretions, as well as for the methods of determining the percentage of HCl in them, the reader is referred to special treatises upon the diseases of the stomach. The tests above given are amply sufficient for all practical purposes.

The presence and, if possible, the percentage of HCl having been ascertained, the gastric secretion is next tested as to its digestive capacity. For this purpose equal quantities of the filtered secretion are placed in each of four test-tubes. To the first nothing more is added; to the second is added two drops of the official HCl of the German Pharmacopœia; to the third from 0.2–0.5 gramme of pepsin; and to the fourth both pepsin and HCl in

the amounts just mentioned. In each of the tubes thus prepared is now placed a piece of hard-boiled white of egg, the size of which must be the same in each experiment. These pieces are prepared by cutting uniform slices of egg with a Valentin knife and then punching out a circular fragment with a cork-punch. The tubes, having been prepared in the manner described, are placed in the incubator and kept at a proper temperature (100° F.). It will soon be determined whether the gastric juice is alone capable of digesting albumen or whether it is deficient in HCl, in pepsin, or in both.

Besides pepsin there is in the gastric juice a ferment ("Labferment" of the Germans) which coagulates milk and which may be conveniently called the rennet-ferment. Its presence is recognized in the following manner: The gastric juice is first neutralized to prevent the curdling action of HCl or other acid, and then added to an equal quantity of boiled neutral-reacting milk. The mixture is placed in the incubator at a temperature of 100° F., and if the rennet-ferment is present coagulation will occur in from fifteen to thirty minutes.

We have now to inquire concerning the practical results thus far derived from these clinical applications of chemistry. Considering that the methods described were introduced but a few years ago by Von den Velden and Leube, these results are remarkable. In the first place, they have led to the division of so-called dyspepsias into three groups:

1. Those characterized by a diminution or absence of HCl—hypacidity or anacidity.
2. Those characterized by an excess of HCl—hyperacidity.
3. A less important group—or, rather, one not yet so well defined—includes those cases in which the presence of HCl is variable.

A knowledge of the absorbent power of the stomach is sometimes of diagnostic value, and may be obtained by the following test, first employed by Penzoldt and Faber: Three grains of potassium iodide are administered in a gelatin capsule, and the saliva, which has been previously demonstrated to be free from iodine, is tested every minute for this substance. In dealing with a healthy and empty stomach the first iodine reaction will be obtained in from six and one-half to eleven minutes. If the drug be administered immediately after a meal, the iodine reaction will not appear until forty-five minutes have elapsed. By this means it has been shown that in various pathological conditions, such as cancer, ulcer, chronic catarrh, and atrophy of the gastric mucosa, absorption is retarded.

It is often of diagnostic value to obtain some idea of the motor power of the stomach, which some authorities are inclined to regard as its most important function. Until quite recently the only method of acquiring such information was that introduced by Leube, and consisted in the introduction of the stomach-tube seven hours after a meal—*i. e.* at a time when the food should have passed into the intestine. The presence of food at such a time would indicate an impairment of motor power, and the degree of the lateness would be in direct ratio to the quantity of the former. This method is crude and inapplicable to most clinical purposes.

The peculiar properties of *salol* led Ewald and Sievers to employ it for testing the motor function of the stomach. This drug remains insoluble and undecomposed in the stomach, but splits up into carbolic and salicylic acids when it comes in contact with the alkaline secretions of the intestine. The salicylic acid is excreted with the urine, in which it may be detected by suitable reagents, and the time between the administration of the *salol* and the detection of the salicylic acid in the urine is indicative of the motor power of the stomach. I mention this ingenious test for the purpose of

showing the direction of present research in the diagnosis of diseases of the stomach, although I believe it can never come into general use. In the first place, the chemical test for salicylic acid in the urine is an elaborate one, and, in the next, it is impossible for most persons to urinate at such frequent intervals as it demands.

Betol has recently been recommended by Fodera and Corselli as an agent for measuring the motor power of the stomach, on the ground that it is less soluble in that viscus than salol. In a healthy man salicylic acid appears in the urine in from seventy to eighty minutes after the administration of betol. A longer interval will therefore show diminished motor activity of the stomach.

The foregoing remarks will obviate the necessity of frequent repetitions, and are indispensable to a proper understanding of the functional diseases of the stomach.—H.]

[Functional Disorders, or Neuroses of the Stomach.

By this term we designate certain disorders of motion, sensation, and secretion, which may exist either singly or combined in various proportions. The chief of them are placed in the following table:

<i>Motor neuroses.</i>	{	Increased motor activity.	{	Nervous vomiting.	
				Peristaltic unrest.	
<i>Sensory neuroses.</i>	{	Diminished motor activity.—Atony.		{	Nervous eructation.
					Rumination.
<i>Secretory neuroses.</i>	{	Gastralgia.	{	Incontinence of pylorus.	
<i>Mixed forms.</i>	{	Polyphagia, Malacia and Pica, Polydipsia, and Dipsomania.	{		
<i>Secretory neuroses.</i>	{	Anacidity.	{		
<i>Mixed forms.</i>	{	Hyperacidity.	{		
<i>Mixed forms.</i>	{	Hypersecretion.	{		
<i>Mixed forms.</i>	{	—Nervous dyspepsia.	{		

MOTOR NEUROSES.

Nervous Vomiting—Emesis Nervosa.

ETIOLOGY.—Nervous vomiting is distinguished etiologically more by its negative than by its positive features. Under this head are included all forms of vomiting which do not depend upon excessive quantity or altered quality of the food or upon organic affections of the stomach, such as catarrh, ulcer, cancer, etc. In a word, the causes of nervous vomiting are all reflex. The irritation which induces emesis may be conveyed by the special senses, especially those of taste and smell—a fact so well known that we are accustomed to speak of certain substances as *nauseous*. It is even said that shrill sounds will induce vomiting in certain hyperæsthetic individuals. It is evident from the foregoing remarks that the so-called nervous vomiting is nothing more than a symptom, which is studied separately, as though it were an independent affection, chiefly to impress its distinctive features upon the mind, and thereby prevent them from diverting the attention from the primary disease.

The chief organs from which the irritation giving rise to nervous vomiting is propagated are those of the central nervous system, the abdomen, and the pelvis.

Disordered states of the cerebral circulation, such as may be produced by a

violent blow on the head, by swinging, by travelling by sea or by rail (especially with the back to the locomotive), are frequent causes of the affection. It is also a well-known symptom of meningitis, cerebral tumors, apoplectic extravasation, and cerebral abscess. It is not uncommon in cases of *tuberculosis dorsalis*, in which disease it may be attended with severe gastralgia, constituting the affection described by the French under the name of *crise gastrique*.

The chief abdominal causes of nervous vomiting are gall-stone, renal calculus, intestinal parasites, hernia, peritonitis, and movable kidney.

Irritations from the pelvis giving rise to this symptom are pregnancy, especially in its beginning, displacements of the uterus, and parametritis. Massive tumors of uterus or ovary are not, as a rule, attended with vomiting. In men, injury of the testicle, epididymitis, and orchitis are frequent causes of vomiting.

Certain causes of nervous vomiting may be called toxic; for example, the forms dependent upon cholæmia and so-called uræmia, as well as the form of vomiting excited by the systemic emetics, such as apomorphia, which will excite emesis when injected beneath the skin, and therefore cannot act as a direct gastric irritant.

Finally, nervous vomiting is the most conspicuous manifestation of certain forms of hysteria, and may persist for years in spite of every therapeutic effort.

SYMPTOMS.—The chief characteristic of this form of emesis is the more or less complete absence of nausea and the ease and rapidity with which the act of vomiting takes place. The food is usually rejected unaltered, and, as a rule, little or nothing is retained in the stomach. In other cases the viscus retains certain of the ingesta and rejects others. Ewald refers to a case in which all solid food was retained, liquids only being vomited. A marked peculiarity of the hysterical form of the disease is that it may persist for years without any perceptible deterioration of the general nutrition; in fact, patients who have vomited after every meal for a protracted period may not only retain their weight, but actually gain flesh.

The tongue often presents a perfectly normal appearance and the appetite may be preserved. The urine is diminished in quantity during the attacks, is of darker color than normal, and of high specific gravity. It often deposits a copious sediment of urates. As a matter of course, when the affection is dependent upon organic disease of brain or spinal cord, or of an abdominal, uterine, or other organ, the symptoms will be complicated by those of the primary disease.

DIAGNOSIS.—This is made by the careful exclusion of organic disease of the stomach, and in many cases by the demonstration of some affection of one of the organs above mentioned. In all cases of obstinate vomiting the urine should be examined, the eye-ground inspected, and the uterus and its appendages carefully explored. Retention of the body-weight, preservation of the appetite, and a clean tongue furnish strong evidence in favor of the view that the vomiting is purely nervous.

PROGNOSIS.—As regards life, the prognosis depends upon the nature of the primary disease when the affection is symptomatic of some underlying affection; while in cases of hysteria life is rarely threatened, although the vomiting may persist for years in spite of the most intelligent treatment.

TREATMENT.—The treatment must be, as far as possible, causal. When the cause persists the symptoms may be ameliorated by administering small

pieces of ice, by the application of an ice-bladder to the epigastrium, or by counter-irritation of the same region. Opium, chloral, ether, and chloroform are often of decided service, and the same is true of nervines such as the bromides, camphor, and musk. Benefit is often derived from large doses of subnitrate of bismuth. Absolute rest in bed should be insisted upon, and nothing be permitted in the way of nourishment except nutritive fluids such as strong beef-essence and milk. In addition, small quantities of champagne and carbonic-acid water may be administered. Koumyss is often retained when all else is rejected. Hypnotism is said to have been efficacious in some cases of hysterical nature.

Hysterical vomiting is undoubtedly largely the effect of habit, and may often be cured by breaking one of the links in the chain of actions which accompany it. My meaning will be rendered plainer by the following extracts from the reports of three cases by Dr. Henry M. Tuckwell.¹

The first was a boy *æt.* 15 who had vomited all his food for about four months, was bed-ridden, greatly emaciated, and pitifully nervous, bursting into tears when spoken to. He was placed on lime-water and milk, which was rejected as soon as the milk was swallowed. The nurse having observed that as soon as the milk was swallowed the boy "raised himself into a half-sitting posture and began to heave," Tuckwell ordered her to prevent this by sitting at the patient's side and keeping him flat on his back after each dose of milk. The result was that the milk was retained, and in a few days he was able to keep down some minced mutton. From this time recovery was rapid, and the patient was soon discharged "fat and cheerful."

The second case was also a boy between 13 and 14 who had been vomiting incessantly for several weeks. The habit in this instance was broken up by compelling him to sit still instead of getting up and leaving the table to vomit, as he had previously done.

The third case was a girl of 14 who was cured by being compelled to lie on her back for half an hour after taking food. For eighteen months previously, with the exception of a three-months intermission, she had vomited her meals, going to the water-closet regularly for this purpose.—H.]

[Peristaltic Unrest (Peristaltische Unruhe).

Under this head is designated an habitual state of increased peristalsis unaccompanied with vomiting or eructation and independent of pyloric stenosis.

ETIOLOGY.—Anæmia and neurasthenia constitute the etiological basis of the affection. The peristalsis is generally most marked just after meals, but does not entirely cease during the intervals.

SYMPTOMS.—The sole symptom of which the patient complains is the rumbling noise which often attends every respiratory or other muscular movement. This is frequently so loud as to be heard distinctly across a large room. The affection is unattended with pain.

DIAGNOSIS.—This is made without difficulty if the physician has an opportunity of hearing the sounds referred to, but, unfortunately, they are apt to cease at the very time of his visit. In this respect hyperperistalsis of the stomach does not differ from many other neuroses. While an attack is in progress the stomach may be seen to contract as in cases of pyloric stenosis. A wave of contraction may be followed with the eye as it slowly proceeds from the cardia to the pylorus.

¹ *British Medical Journal*, March 22, 1873.

TREATMENT.—The treatment of this annoying affection consists of a careful regulation of the diet and a judicious management of the underlying constitutional state. I have found this peristaltic unrest to be a frequent symptom of chlorosis, and have observed it to disappear as the state of the blood improves. A brief course of rest-treatment is often of decided benefit, the patient being put to bed and kept absolutely quiet while the circulation is stimulated with massage and the muscles exercised with electricity. Warm cataplasms to the abdomen are useful in allaying the hyperactivity of the gastric muscles.

The **TREATMENT** of this harmless affection should be seriously undertaken for the existence of many a woman is rendered unhappy by the explosions which attend it, and which occur on the most inopportune occasions.—H.]

[Nervous Eructation.

ETIOLOGY AND SYMPTOMS.—Hysteria, hypochondria, and neurasthenia are the underlying causes of this affection, which may exist alone or combined with other manifestations of a disordered nervous system. It is said by Ewald to be a characteristic of the hysterical form of eructation that it is not attended with other symptoms referable to the stomach, while in the other neurasthenic forms of the affection there are, in addition, sensations of weight, fulness, and tension in the epigastrium. Pain is not an attendant of any variety of the complaint.

The attacks are recognized by their paroxysmal character as well as by the nature of the gas belched up. The latter is odorless and tasteless, and is shown by chemical examination to be nothing more than atmospheric air which has undoubtedly been swallowed with the food and drink or forced down, independently of the acts of eating or drinking, by peculiar movements of deglutition. The number of eructations is sometimes enormous, as many as 2500 having been counted in one hour. During the paroxysms the stomach may either be distended or not. In the latter event it is probable that the gas is brought up from the œsophagus, for Ewald has demonstrated that gas may be forced by acts of deglutition into this canal without necessarily passing through the cardiac orifice of the stomach.

PROGNOSIS AND TREATMENT.—The prognosis is intimately bound up with that of the underlying neurosis, and the treatment is essentially the same as that of the "peristaltic unrest" of the stomach just described.—H.]

[Rumination—Merycismus.

(*Merycismus*, "to chew the cud.")

DEFINITION.—Rumination is the voluntary regurgitation of food from the stomach for the purpose of remastication. It differs, therefore, materially from simple regurgitation, which consists of the involuntary eructation of food, which is either swallowed again immediately or is ejected from the mouth.

With reference to the mechanism of rumination—or, rather, of the regurgitation which is the first step in the process—it has been observed that it is always preceded by a rapid inspiration and an equally rapid expiration. The effect of the first is to draw the food by suction through the cardiac orifice, which is simultaneously relaxed, and that of the second, to prevent its return into the stomach. This view of the nature of the process has been confirmed experimentally by Flourens, who was able to render the act of rumination in the sheep difficult or impossible by section of the phrenic

nerves and of the medulla spinalis at the level of the sixth dorsal vertebra, the effect of this operation being to paralyze the chief muscles of respiration.

ETIOLOGY.—In the etiology of this disease heredity and imitation play important rôles. It was supposed by most of the medical writers of the seventeenth century, previous to which we have no records of the disease, that the victims of the habit of rumination were descended from cornigerous parents, or were themselves either possessed of horns or, like other ruminants, were provided with more than one stomach. Strange to say, two of the earliest cases on record¹ occurred in men who had horny growths on their foreheads, but who nevertheless, as demonstrated post mortem by Fabricius of Acquapendente, had each but one stomach.

Heredity, nevertheless, is of undoubted influence, as is shown by the reports of several cases contained in the elaborate article upon this subject by Bourneville and Séglas.² The same writers give instances of the origin of the disease through mimicry, of which the following is the most striking: Two children, a boy of six and a girl of three, acquired the habit of rumination from their governess, who was addicted to it. The children were cured by the dismissal of their teacher. Other cases of supposed mimetic origin are more apocryphal; for example, a ruminating child of seven who had been suckled by a goat, and a man who had spent his life among cattle.

The influence of sex is decided. Of 35 cases reported by Bourneville and Séglas, only 5 were females.

The irritation of the stomach by unmasticated food and indigestible substances is an undoubted cause of the habit of rumination, and accounts for its prevalence among idiots.

The effect of irritation in producing regurgitation is exemplified by an experience of the distinguished physiologist Brown-Séquard. In the course of some researches upon digestion he was led to practise upon himself an experiment first performed by Spallanzani, which consisted in swallowing a small sponge attached to a thread for the purpose of obtaining a sample of gastric juice. He soon became unable to retain the sponge for the short period required, and was obliged to desist from further auto-experiments in this direction; but for some time afterward, much to his annoyance, the food continued to be regurgitated.

ANATOMICAL APPEARANCES.—There is no uniformity in the post-mortem appearances. The stomach has been found dilated in some cases, perfectly normal in size and shape in others, while the cardiac orifice may be either unusually patent or in no way altered. A dilated cardiac orifice may be an effect as well as a cause of the disease.

SYMPTOMS.—The interval between the repast and the act of rumination is not constant. It may vary between a few minutes and an hour, but in the average begins about fifteen minutes after eating. The food is returned to the mouth in an almost unaltered condition, and seems to be enjoyed with a keener relish than when first swallowed.³ This probably accounts for the time consumed in this second mastication, which has been observed to extend to several hours. Many of those addicted to the habit practise it after every meal, while others do so only upon special occasions—for example, when

¹Vide A. Johannessen, "Ueber das Wiederkäuen beim Menschen," *Zeitschrift für klin. Med.*, Bd. 10, S. 274.

²"Du Mérycisme," *Archives de Neurologie*, 6 and 7, 1883.

³"Indeed, it is sweeter than honey and accompanied with a more delightful relish."—Anthony Rechy. I have been unable to verify this quotation, which is from Ewald.

they have bolted their food with unusual haste, or have consumed an inordinate quantity, or have taken severe exercise immediately after eating.

The general health is usually well preserved. In other cases signs of gastric catarrh manifest themselves, this being generally due to the fact that even the second mastication is too hastily performed. When this complication ensues the patient complains that the taste of the regurgitated food, previously agreeable, has become sour or rancid. The health continues good so long as the food remains pleasant to the taste, is thoroughly remasticated, and is again swallowed.

DIAGNOSIS.—There is no difficulty about the diagnosis of this condition. From simple regurgitation it is distinguished by the unaltered character of the food and the regular recurrence of the process after meals; also by the absence of signs of gastric catarrh or dilatation.

PROGNOSIS.—The prognosis is good as to life and health, and as to recovery also when the patient is willing and able to co-operate with the physician.

TREATMENT.—Patients with this affection should be directed to eat slowly, to masticate their food thoroughly, and to endeavor by an effort of the will to repress the muscular movements associated with the habit. This may be aided by the dorsal decubitus or some other position unfavorable to the performance of the act. Bulky food, such as vegetables and bread, is inadmissible, and the diet should consist for a time chiefly of nutritive fluids. The ingestion of small pieces of ice after meals has been attended with benefit, and is supposed to act by improving the tonicity of the stomach. Tonics and purgatives have seemed of service in some cases, and probably exert their beneficial action upon any underlying state of asthenia that may be present. Strychnine should be given a thorough trial. Bourneville and Ségliis are of the opinion that where the affection has existed for many years without impairment of health, it is unwise to attempt to suppress it; but surely the risk of a temporary impairment of health should not be admitted as an excuse for persisting in so disgusting a habit.—H.]

[Incontinence of the Pylorus.

DEFINITION.—For the proper performance of gastric digestion it is essential that the chyme be retained for a certain period in the stomach. The result of its premature escape is irritation of the intestinal mucosa and consequent diarrhœa. Such a condition has been described by Ebstein, and is mentioned more for the sake of completeness than for any practical value that has been derived from its study. In fact, its interest is decidedly more theoretical than practical, as may be inferred from the fact that Ewald, whose experience and knowledge of gastric disease is universally acknowledged, declares that he is not acquainted with the condition described by Ebstein. Such a statement, of course, applies solely to the functional form of the affection, for the form of pyloric incontinence resulting from ulceration of a tumor in this region is recognized by all.

According to Ebstein, incontinence of the pylorus may be recognized by the fact that gas generated artificially in the stomach by chemical means or injected into the organ by means of an atomizer does not give rise to gastric dilatation, but, on the other hand, distends the intestines. He accounts for the absence of dilatation of the stomach in such cases by the hypothesis that the pyloric fibres yield with abnormal readiness and permit the gas to escape into the duodenum. The escape of the gas from the stomach *via* the pylorus

is said to depend upon its nature, carbonic acid being retained longer in the organ than atmospheric air. This is believed to be due to a greater irritation of the pyloric muscular fibres by CO_2 .

Further study is needed before incontinence of the pylorus can be accorded a definite clinical rank among the diseases of the stomach.

Atony.

Atony as a separate disease is an inference rather than an actual recognition. We recognize it, as already seen, as the first stage of atonic dilatation, but only when that stage is past. The motor function of the stomach is doubtless impaired in many cases of neurasthenia, but the functions of secretion and absorption are so intimately bound up with that of motion that it is doubtful whether atony has an independent existence. It may be recognised by the salol-test, previously described.—H.]

SENSORY NEUROSES.

Gastralgia.

Gastralgia, called frequently gastrodynia, is a neuralgic affection characterized by pain, more or less intense, referred to the region of the stomach. Pain is a symptom of gastritis, carcinoma of the stomach, and gastric ulcer; it also enters into the clinical history of dyspepsia, especially the variety called acute dyspepsia, and a peculiar character of pain constitutes the dyspeptic symptom called cardialgia or heartburn. But, considered as characterizing a distinct functional affection, the pain is not necessarily incidental to inflammation or any appreciable lesion, nor is it always, although frequently, associated with dyspeptic disorder; in short, gastralgia exists when pain and other circumstances denote an affection of the same pathological character as neuralgia in other situations.

Gastralgia is presented in practice in two forms: in one form a severe attack of pain occurs, and if not relieved by remedies it continues for several hours or even days. The pain is often excruciating, subduing the strongest resolution. The patient writhes and groans with intense suffering. A sense of constriction frequently accompanies the pain. Vomiting may occur, but this is rare. Generally, tenderness over the epigastrium is wanting, and some relief may be afforded by pressure. The paroxysm is not attended with pyrexia, and the skin may be bathed in perspiration from the intensity of pain. These attacks are generally attributed to spasm or cramp, and the affection has been called colic of the stomach. It is difficult to say how much of the suffering is due to spasmodic contraction and how much to neuralgic pain. Practically, it is not important to make this discrimination. This form of gastralgia may be distinguished as *acute*.

Such attacks in some persons are produced by certain ingesta. Strawberries, for example, have been known to prove in this way poisonous, and I have met with a patient who had always an attack after eating honey. He came under my observation when suffering from an attack thus produced. These, like other idiosyncrasies, are inexplicable. Attacks appear to be sometimes attributable to exposure to cold and to fatigue from over-exertion.

This form of gastralgia is readily discriminated from acute gastritis. The pain may be much more intense than in cases of the latter disease. As a rule, the tenderness over the epigastrium which belongs to the history of gastritis is wanting. Vomiting may be wanting, and if present is not as prominent a symptom as in gastritis. The absence of pyrexia is an important point in the exclusion of gastritis. The passage of gall-stones, or hepatic

colic, offers many symptoms in common, and the discrimination is not at once readily made. The points involved in the differential diagnosis will be considered presently in treating of the passage of gall-stones. In the diagnosis of gastralgia attacks of angina pectoris are to be excluded. (Vide p. 284.)

Although, as a rule, acute gastralgia occurs irrespective of inflammation or any appreciable lesion, it is sometimes associated with either gastric or duodenal ulcer. The existence of ulceration is liable to be overlooked if the diagnostic symptoms be not marked. This statement is especially true of duodenal ulcer. In several cases which have come under my observation profuse hemorrhage has followed attacks of gastralgia.

Attacks of severe gastralgia, recurring after interruptions of variable duration and accompanied by vomiting, are described by Charcot, under the name *gastric crises*, as associated with locomotor ataxia. They may be associated with other affections of the spinal cord.¹

This form of gastralgia is to be treated by opiates carried to the extent of procuring relief. A quarter or a half of a grain of a salt of morphia may be sprinkled on the tongue, and this dose repeated, if necessary, after the lapse of from half an hour to an hour, until the pain is relieved; or the same course may be pursued with other forms of opiate. If the opiate be rejected from the stomach, it may be given *per enema*. The hypodermic mode of administration is well suited to this affection, as to all affections in which it is desired to produce quickly and efficiently an anodyne effect. This plan of treatment is not to be deferred for the operation of a cathartic or an emetic even if the attack be attributable to dietetic cause. A sinapism and fomentations to the epigastrium are useful as auxiliary measures. An alcoholic stimulant may be added with advantage if not contraindicated by vomiting, especially if the pulse be feeble and the surface cold. Rest, regulated diet, and a mild cathartic or laxative, provided the bowels do not act spontaneously, will constitute the subsequent treatment.

Although the suffering is as great as in any other affection, there is little or no danger. It may be doubted whether this affection alone ever prove fatal; and the practitioner may count with confidence on procuring speedy relief by means of the plan of treatment just stated. The affection, therefore, is one of those which exemplify in a striking manner the resources of medicine.

Chronic gastralgia is another form of the affection. The pain is either limited to paroxysms which recur more or less frequently, or it is habitual, with exacerbations at variable intervals. The pain varies much in different cases as regards intensity, and also in different paroxysms or exacerbations in the same case. It may have so little intensity as to occasion only annoyance, or it may be so severe as to give rise to extreme suffering. The character of the pain is described by patients as burning, lancinating, or gnawing. Frequently the pain extends from the epigastrium in different directions—namely, to the back, into the chest, and laterally into the right and the left hypochondrium.

With the affection in some cases are associated dyspeptic ailments, and in other cases there is no disorder of digestion. Paroxysms or exacerbations sometimes appear to be provoked by the ingestion of food, but as a rule relief of pain is felt after eating. The desire for food is oftener increased than diminished. Generally, tenderness over the epigastrium is wanting, and pressure frequently affords relief. The decubitus during the suffering from pain is sometimes upon the belly. Constipation exists much oftener than looseness of the bowels. Flatulent distension of the stomach or intes-

¹ Vide article on "Gastric Ulcer" by Prof. Welch in the *System of Practical Medicine*, by American Authors, vol. ii. p. 517.

tine is sometimes associated. The pulse preserves its normal frequency and the temperature of the body is not increased. Patients who have suffered from the malady for some time are likely to become melancholic and hypochondriacal. I have known it to be associated with a tendency to suicide.

Gastralgia rarely if ever occurs before the age of puberty or in old age. It is generally considered that women, much more than men, are liable to it, but of 39 cases analyzed by Valleix only 20 were females. It affects those of good constitution and the robust as well as the feeble and delicate. Persons of sedentary habits are more likely to be affected than those engaged in active pursuits. Prolonged mental depression has been supposed to favor its occurrence. It appears in some cases to depend on the gouty diathesis. Like neuralgia in other situations, it may be an effect of malaria; and attacks of gastralgia may recur with the regularity of the paroxysms of intermittent fever. I have known gastralgia to take the place of the cold stage of the paroxysm, being followed by the hot and the sweating stage. Finally, causes which induce anæmia or lead to debility may be more or less involved in its production.

The DIAGNOSIS of the chronic form of gastralgia is to be based on certain distinctive characters—namely, the occurrence of pain, either in paroxysms or marked exacerbations; the relief frequently afforded by pressure and the ingestion of food; the persistence of appetite in many cases; and not infrequently the absence of disorder of digestion and of pyrexia. These points in the history are involved especially in the discrimination of gastralgia from subacute or chronic gastritis. The diagnosis involves the exclusion of gastric ulcer and cancer. These affections are to be excluded by the absence of their diagnostic symptoms, irrespective of pain. In some cases of intercostal neuralgia pain is referred to the epigastrium. This affection is excluded by the absence of its diagnostic criterion—namely, tenderness on pressure over three points, posteriorly, laterally, and anteriorly. (Vide p. 98.)

Chronic gastralgia is likely to be persisting. Its duration in different cases is extremely variable. In this respect it resembles other neuralgic affections. It may continue for many months, and it sometimes persists for many years. As regards prognosis, the worst to be apprehended is the persistence of the affection. It does not tend to destroy life either directly or by eventuating in some other more serious disease. It is not prudent for the practitioner to predict that the affection will end speedily or within any definite period, yet not infrequently it does not continue. In certain cases it is one of the affections most rebellious to therapeutical measures, but in other cases it is readily amenable to treatment.

In the TREATMENT of gastralgia clinical experience has abundantly shown certain measures formerly in vogue to be not only ineffectual, but prejudicial. This remark has reference to general and local bloodletting, emetics, mercurials, purgative remedies, and perhaps also vesication or other modes of active counter-irritation. Anodyne remedies are frequently called for to relieve pain. If the pain be severe, opium can hardly be dispensed with; but in this, as in other painful affections which are likely to be persisting, the liability to the formation of a habit of using opium is to be considered. Moreover, the use of opium, aside from the palliation of pain, is objectionable on account of its interference with the appetite and digestion, and in this way it may contribute to perpetuate the affection. Opium is therefore to be used with circumspection, and when practicable other palliative measures are to be substituted, such as belladonna, hyoscyamus, etc. Fomentations and embrocations containing opium, chloroform, aconite, etc. will sometimes succeed in affording relief. Cold applied to the epigastrium has been found effectual. Certain remedies appear in some cases to exert a curative influence. Bis-

THE EFFECT OF THE LIVER ON THE DIGESTION AND ABSORPTION

The liver is a large, soft, reddish-brown organ, situated in the upper right quadrant of the abdomen, just below the diaphragm. It is the largest gland in the body, and its functions are many and varied. One of its most important functions is the production of bile, which is secreted into the gallbladder and then into the small intestine. Bile is essential for the digestion of fats, and its absence would result in severe malabsorption. The liver also plays a role in the metabolism of carbohydrates, proteins, and fats, and in the storage of glycogen and vitamins. In addition, it is involved in the detoxification of drugs and poisons, and in the production of blood proteins. The liver's ability to regenerate itself after injury is another remarkable feature. The liver's connection to the digestive system is highlighted by the fact that it receives blood from the stomach, small intestine, and pancreas via the portal vein. This blood carries nutrients and toxins to the liver, where they are processed before being distributed to the rest of the body. The liver's role in the digestive process is thus both direct and indirect, and its health is crucial for overall well-being.

amount of food craved far exceeding the requirements for nutrition. Bulimia may be another name for gluttony. The love of eating may be cultivated to such an extent that little else is thought of, and persons who fall into this habit may be said to live to eat, rather than to eat to live. The observation of every one will furnish examples of this kind. Habits of gluttony may lead to dyspepsia, which, by interrupting further indulgence, proves conservative, or, if the digestive function continue active, they may lead to obesity, fatty degeneration of the heart or other organs, and to various affections. Voracious eating characterizes certain cases of mental derangement. It may be a symptom of disease attended with progressive waste; as, for example, diabetes. In a more marked and rare form the craving for food greatly exceeds that under the circumstances just named. Curious instances have been reported in which the morbid appetite appeared to be insatiable, all kinds of food—raw meat, candles, etc.—being eaten in some cases with avidity and in enormous quantity. It is difficult to explain the morbid appetite in these instances. Recovery from this condition is to be expected. The indications are to regulate the diet as far as possible, to establish the general health by hygienic measures, to correct any disorder of digestion which may exist, and to palliate the excessive craving for food by opium, or sometimes by nauseant remedies. Swallowing pieces of ice has been found effective as a palliative measure.

Malacia and *pica* are terms applied to perversions of appetite; that is, to a morbid craving for particular substances. The terms are commonly used as synonyms, but strictly they denote different kinds of perversion. *Malacia* denotes a morbid craving for certain articles of food or articles which are not devoid of nutrition, whereas *pica* denotes a desire for innutritious substances. The craving for strange kinds of food sometimes attending pregnancy, and commonly known as "longings," is sufficiently familiar. Similar eccentricities of the appetite are sometimes observed in connection with hysteria, and they may be due in some cases to that desire to become objects of wonder or interest which weak-minded hysterical women sometimes present. Unnatural and disgusting perversions of the appetite are among the symptoms occasionally met with in cases of insanity. Perversions falling under the head of *pica* are sufficiently common. Innutritious substances frequently craved are charcoal, chalk, slate, and certain kinds of earth. The habit of eating these substances is sometimes carried to a great extent. In the case of a young woman seized shortly after marriage with epidemic dysentery, which proved fatal, the dejections contained an enormous amount of a black substance which on investigation was found to be from a species of slate-stone which she was accustomed to eat daily in excessive quantity. In some cases of *pica* the articles are at first taken with the idea of improving the complexion, and in this way the habit is formed; but in other cases a morbid uneasiness in the stomach leads to their use. The appetite is chiefly confined to females, especially young girls, and is generally associated with anæmia or chlorosis. The measures of treatment are to be addressed to the associated disorders, the continued indulgence of the perverted appetite being interdicted.

Dirt-eating, as it is vulgarly called (*chthonophagia*), is a morbid habit which heretofore prevailed to a considerable extent among the plantation negroes of the Southern States. It was described by John Hunter as prevailing among the negroes of the West Indies. The kind of earth selected is a loam or clay. Duncan gives the following account of this form of *pica*: "A very common disease among negroes on plantations in this part of the country (Louisiana) is a state of anæmia very often attributed, and perhaps justly, to the pernicious habit of dirt-eating. On examining negroes on a plantation a medical man is surprised to meet with so many of these cases. Almost every large plantation has three or four, and sometimes more of them. . . .

With many, no doubt, dirt-eating is a symptom only of a diseased condition of the digestive organs and of the system generally. With them dirt-eating proceeds from the same propensity which leads white females to resort to chalk, magnesia, etc. in order to relieve a disordered acrid condition of the stomach. This condition of system is often, in my opinion, produced by a deficiency of suitable nutriment."¹

Polydipsia is a term used to denote a condition characterized by an excessive craving for liquids. Water is drunk in a very large or enormous quantity, amounting sometimes to several gallons in the twenty-four hours. In some cases the patient experiences constant or frequently recurring thirst, associated with dryness of the tongue and fauces. There is inability to sleep, except for short periods, in consequence of the urgency of the desire for drink. The quantity of urine is proportionately great, so that this condition is also denoted by a term expressing the latter fact—namely, *diabetes insipidus*. The urine voided is of low specific gravity, presenting a clear, limpid appearance like pure water, and containing neither sugar nor any abnormal constituent. In other respects the health may not be notably disordered. The appetite and digestion may be unimpaired, the functions generally are well performed, and the body does not waste. This condition at first suggests to the physician the probable existence of diabetes mellitus, but an examination of the urine leads to the exclusion of the latter disease. The condition may occur in early life or become developed at any age. It has been observed to occur as an intermittent malady, but in general it continues for an indefinite period or during life. It does not appear to lead to any disease, and is serious in itself only on account of the annoyance and debility which it occasions. Its pathological character, with our present knowledge, cannot be satisfactorily explained. Existing to the extent just described, it is so rare as to belong among the curiosities of clinical experience. In our ignorance of the pathology there are no rational indications for treatment, and experience has not furnished any reliable means of cure. Opium, valerian, camphor, and other antispasmodics have been found to diminish the thirst temporarily, and some benefit has been derived from the use of various tonic remedies.

Dipsomania is a term sometimes used to denote the peculiar delirium arising from the abuse of alcohol, but it is commonly applied to an uncontrollable desire for alcoholic drinks. A craving for this class of stimulants is sometimes developed in cases of dyspepsia, and may prove a source of intemperate habits. This fact has been already referred to. It is not to be lost sight of in judging of the propriety of prescribing or sanctioning the use of alcoholic stimulants in dyspeptic cases. A morbid craving for alcohol in some form is an element of intemperate habits whatever may have been their source. The habitual drunkard feels a desire for continued indulgence, which, with an impaired power of self-control and lessened self-respect resulting from intemperance, he is after a time wholly unable to resist. It is useless under these circumstances to attempt to reason him into temperance; he may appreciate the force of all the arguments which are presented, but he lacks moral strength enough to govern an acquired appetite which represents a morbid condition as much as the delusions of insanity. Reason and persuasion, however, may be effective before this condition of dipsomania is reached; that is, they may prevent this condition by leading to abstinence from alcoholic stimulants. Dipsomania is to be treated as a disease of body and mind. The cure is to be effected by withdrawing the patient from the use of alcohol in any form, and by the employment of medicinal and hygienic measures to invigorate the physical and mental faculties. The treatment

¹ Fenner's *Southern Medical Reports*, vol. i.

must be continued long enough for the cessation of the morbid craving for stimulants and for the development of moral strength sufficient to enable the patient to adhere to a course of total abstinence, in which alone consists safety. It is evident that successful management is rarely practicable, except by means of institutions in which the patient is under the same restrictions as in insane asylums. In fact, dipsomania is to be treated as a form of mental derangement.

There is a species of dipsomania which is constitutional and congenital. The desire for stimulants is paroxysmal, and an irresistible craving is developed by any indulgence, however small. Persons with this idiosyncrasy lose their power of self-control as soon as they feel the influence of alcohol. The only protection in such cases is in rigid abstinence.

Connected with the subject of dipsomania are questions pertaining to the causes of intemperance and the means of its prevention which are of the utmost importance to the welfare of mankind, but which do not properly fall within the scope of this work. The morbid effects of alcohol upon the system, aside from the development of dipsomania, will be referred to in connection with different individual diseases, especially those affecting the nervous system.

[SECRETORY NEUROSES.]

These consist of anacidity and hyperacidity—meaning thereby an absence of HCl from the gastric juice, an excess of the same therein, or the secretion of gastric juice by a fasting stomach.

Anacidity has been already discussed in connection with Cancer of the Stomach, and was shown to be decidedly diagnostic of that disease. It may, however, occur as a pure neurosis, and for a time give rise to great uncertainty with reference to its true nature. Coexisting symptoms of hysteria and neurasthenia point strongly toward a neurotic origin of the condition. In some cases, however, nothing but time will conclusively settle this diagnostic question.

Hyperacidity and Hypersecretion.

These conditions, which have been already alluded to on a previous page, are due to a too-liberal response of the glands of the stomach to the physiological demands of the food. The conditions are not identical, although the border-line between them is ill defined. Hyperacidity consists in a too-liberal response to a physiological summons, while hypersecretion is, so to speak, gratuitous. In other words, the secretion of gastric juice during stomach digestion is in the former instance hyperacid, and probably also excessive in amount, while in the latter the secretion is poured out uselessly into an empty stomach. Hyperacidity is most frequently observed in connection with gastric ulcer, and therefore scarcely comes under the head of a neurosis. Hypersecretion, on the other hand, is a functional nervous disorder consisting of the exaggeration of normal processes, for, as demonstrated by the researches of Rosin,¹ the fasting stomach contains an appreciable amount of gastric juice. The limits within which the secretion of gastric juice by a fasting stomach may be considered physiological are as yet unknown. It is certain, however, that the functional gastric disorder known as hypersecretion constitutes a well-marked pathological condition. The recognition of hypersecretion is usually ascribed to Reichmann in 1882, and he was undoubtedly the first to study it thoroughly according to modern methods; but, as Ewald points out, it was recognized in 1820 by Pemberton,

¹ *Deutsche med. Wochenschrift*, November 22, 1888.

who speaks of "a morbidly increased secretion from the stomach, analogous to a diabetic secretion of urine by the kidneys." Somewhat later it is evident that Copland and Budd are familiar with this condition. The former speaks of pyrosis as "produced by the continuance of the secretion of the gastric juice after the food taken into the stomach has passed into the duodenum," and Budd remarks that "pain may be due to the presence of free acid in the empty stomach."

SYMPTOMS.—The principal symptoms of hypersecretion are increased thirst, acid eructations, nocturnal attacks of epigastric pain, and dilatation of the stomach. The digestion of carbohydrates is greatly impaired, while that of the albuminous substances proceeds with abnormal vigor. Positive proof of the condition is afforded by the sound, employed in the following manner: The stomach is thoroughly washed out in the evening and the patient directed to fast until the following morning, when the sound is again introduced. If hypersecretion exists, a quantity of fluid varying from eight ounces to a pint may be withdrawn. This fluid is colorless or slightly greenish, of viscid consistency, strongly acid—the acid being HCl—and digests albumen rapidly. In a word, it is gastric juice.

Hypersecretion is always caused by disordered gastric innervation, and occurs in two forms, the one continuous, the other paroxysmal. The latter is often a feature of the "*crises gastriques*" of *tabes*.

TREATMENT.—The chief features of the treatment are the methodical washing out of the stomach, preferably just before the principal meal, and the employment of alkalies and alkaline mineral waters. In no other affection is lavage of the stomach more beneficial. The diet should consist almost entirely of albuminous substances, and the thirst, often excessive, may be assuaged by bits of ice, for it is an important point that the dilatation of the stomach so frequently present should not be maintained by a too-free ingestion of fluid. So important is this considered by Riegel that he advises the use of small doses of opium to obtund an overpowering sense of thirst. To obtain good results from alkalies in this affection, they must be given in large doses, for, as is well known, a small dose of an alkali is followed by an increased secretion of gastric juice. Sir William Roberts of Manchester, observing a profuse flow of saliva in cases of "acid dyspepsia," to which he himself was subject, and believing this to be a provision of nature for relieving the surplus activity of the stomach, recommends in such cases the use of sialagogues, such as gum lozenges containing a small amount of ginger, cayenne pepper, or pyrethrum. He has thus experienced relief in his own person, and given it to others.

MIXED FORMS.

Nervous Dyspepsia.

ETIOLOGY.—Nervous dyspepsia has acquired a permanent position in nosology since its introduction by Leube in 1879,¹ although his conception of the affection has undergone some decided modifications. Leube supposed the chemistry of digestion to be always normal in nervous dyspepsia, whereas numerous exceptions to this rule are now recognized. For example, the states of anacidity, hyperacidity, and hypersecretion above described, when unassociated with any demonstrable gastric lesion, are merely symptoms of nervous dyspepsia. A certain number of cases, however, undoubtedly come under Leube's too-exclusive definition, and can only be ascribed to an abnor-

¹ *Deutsches Archiv für klin. Med.*, Bd. 23, 1879.

mal excitability of the sensory gastric nerves. With improved methods of research an anatomical basis for all these apparently functional disorders may yet be discovered, and there can be no doubt that a certain number of them are due to degeneration of the nerves supplying the stomach. The remarkable observations of Jürgens have established this fact beyond question. In 41 cases in which during life there had been vague symptoms of gastric disorder such as would be ascribed to nervous dyspepsia, Jürgens found total degeneration of Meissner's and Auerbach's plexus.

Nervous dyspepsia seldom exists alone, but is in most instances a part of a general state of neurasthenia or a reflex manifestation of cerebro-spinal or uterine disease or intestinal parasites. It may also depend upon constitutional states such as anæmia, chlorosis, syphilis, and malaria. A certain number of cases are undoubtedly toxic, and depend upon uræmia, lead-poisoning, or the excessive use of tobacco.

SYMPTOMS.—The chief symptoms are eructations—which, unlike those of gastric catarrh, are mostly tasteless and odorless—a sense of fulness and pressure in the epigastrium, and pain which is often independent of the nature of the food. A glass of water even may give rise to pain. As a rule, however, the discomfort after eating is most marked after the principal meal of the day, and is most readily induced by fatty and acid articles of food. Pyrosis is a symptom of nervous dyspepsia, and is sometimes peculiar in being associated with a sub-acid state of the secretions. Vomiting is rare, and when it occurs the matters vomited consist mostly of small quantities of mucus mingled with bile and undigested articles of food, to which a bitter taste is imparted by peptone, and not, as usually supposed, by bile. A capricious appetite is a characteristic feature of many of these cases. There may be complete anorexia alternating with periods of hyperorexia or boulimia. This morbid appetite may suddenly manifest itself at the most unreasonable hours, as in a case reported by Decker¹ in his excellent article on dyspepsia. The individual in question was constantly roused from sleep by a sense of hunger which he was obliged to appease with a hearty meal composed of soup, eggs, cold beef, etc. Insomnia is a frequent symptom of the disorder, whereas, on the contrary, in quite as many cases the patient is habitually drowsy. Mental lassitude, low spirits, and loss of memory are frequently complained of. With reference to the stools, there is nothing characteristic beyond the fact that they are seldom regular, a state of constipation often alternating with diarrhœa.

DIAGNOSIS.—The diagnosis is made by the exclusion of cancer, ulcer, and catarrh. The chief difficulty is in distinguishing this condition of neurasthenia from one of chronic catarrh, but there are certain points which, if borne in mind, will prove of great value in this differential diagnosis. In catarrh the feelings of pressure and fulness are experienced directly after eating and reach their maximum when digestion is at its height, whereas in nervous dyspepsia these symptoms are very variable with reference to the time of their appearance, and are often relieved by eating. They may also disappear for weeks or even months. The appetite in nervous dyspepsia is, as already stated, capricious, whereas in catarrh it is permanently absent. The degree of anæmia is never so great as that commonly present in cases of cancer, and the pain differs from that of ulcer in being more diffuse. The absence of hæmatemesis is important negative evidence in favor of nervous dyspepsia, and the presence of symptoms of general neurasthenia is strongly corroborative of its existence.

¹ *Münchener med. Wochenschrift*, May 28, 1889.

PROGNOSIS.—The prognosis should always be made with reference to the presence of coexisting nervous derangement or peripheral nervous irritation. Pronounced symptoms of nervous dyspepsia have ceased on the expulsion of a tapeworm or the relief of uterine disease. As a rule, the affection is apt to become chronic, and when apparently cured is liable to recur.

TREATMENT.—The treatment of nervous dyspepsia must vary with the cause producing it. One case will be cured by restoring the uterus to its normal position; another, by relieving a chronic constipation or expelling a tapeworm; still another, by allaying an irritation of the spine. A restricted diet or one of milk only, which is frequently beneficial in catarrh, is of little or no benefit in cases of nervous dyspepsia. General supporting measures, massage, electricity, the bromide salts, and, if anæmia exists, arsenic and a mild, non-constipating preparation of iron, such as the albuminate or potassium-tartrate, are the chief indications. The chlorine salts of iron are believed by Ewald to be especially useful in cases of anæmia associated with nervous dyspepsia. The sesquichloride may be given in pill with quinine and arsenic, the latter preferably in the form of arsenic acid, as recommended by Liebreich. This form of arsenic seems to be better tolerated than the solution of Fowler so commonly prescribed.

Of topical measures, the best is lavage with warm water, which often proves remarkably soothing to a hyperæsthetic mucosa. The certain relief which may be derived from opiates, chloral, and occasionally from cocaine, is attended with so great risk as regards subsequent addiction to the use of these drugs that they should be prescribed only to meet temporary indications or be dispensed with altogether. Remarkable results have been obtained in these cases by the rest-cure as inaugurated by Weir Mitchell and adopted by Playfair in England and Burkart, Leyden, and others in Germany. Without entering into minute details, this treatment may be said to consist of absolute rest, mental and bodily, isolation from over-sympathetic friends and relations, passive exercise in the form of massage and faradization of the muscles, and a diet which is carefully regulated as to quality and steadily increased in quantity up to the point of tolerance. The best test of this method is the scales, which, if it is successful, show a rapid gain in weight. If the bodily weight does not speedily increase, the method should be abandoned; but such a contingency can scarcely result from anything but a mistaken diagnosis.—H.]

[The two following articles are retained among the functional diseases of the stomach, where they were placed by the author. Strictly speaking, they are misplaced, and yet their consideration in this connection is most natural, both being prominent symptoms of various diseases of the stomach and other organs.—H.]

Gastrorrhagia.

Hemorrhage into the stomach and vomiting of blood are denoted by the term *hæmatemesis*. The term *gastrorrhagia* is in uniformity with the rule of nomenclature by which a hemorrhage and its situation are expressed, and is therefore to be preferred. Moreover, the term *gastrorrhagia* applies to all cases of gastric hemorrhage, whether vomiting take place or not, the blood sometimes not being expelled by the mouth, but passing into the intestinal canal and being evacuated from the bowels. In the great majority of the cases in which hemorrhage takes place into the stomach, blood is vomited, and, more or less blood also passing into the intestinal canal, the stools present appearances to be described under the head of *Enterorrhagia*.

When blood is expelled from the mouth the first point is to ascertain the

source of the hemorrhage. It may be from the mouth or posterior nares. Coming directly from either of these sources, it is traced without difficulty; but if blood be swallowed and vomiting occur, it may sometimes be a question whether gastric hemorrhage exist or not. In cases of bronchorrhagia blood may be swallowed and vomited. In a child too young to expectorate bronchial hemorrhage might thus be supposed to be gastric. Although instances both of bronchorrhagia and of gastrorrhagia in young children have been recorded, such an occurrence is very rare. The rupture of an aneurism into the pharynx or œsophagus is another source of hemorrhage which may appear to be gastric; but in general the question is whether the blood come directly from the stomach or the air-passages. The points involved in this differential diagnosis have been already presented in treating of bronchorrhagia.¹ Blood which has been vomited in most cases presents a dark, grumous appearance. Exceptionally it is florid, like arterial blood. It then comes from an artery, and is vomited as soon as it accumulates within the stomach.

Gastric hemorrhage in the vast majority of cases has no claim to be regarded as an individual affection. It may be a symptom of carcinoma of the stomach or of gastric ulcer, and as such has been already considered. It is an effect of portal congestion in cases of cirrhosis of the liver and of obstruction of the vena portæ from a thrombus or the pressure of a tumor. It may be caused by aneurisms or by varices of the gastric blood-vessels. It coexists with hemorrhage in other situations in cases of purpura hæmorrhagica and scorbutus. It occurs in cases of acute gastritis, in acute yellow atrophy of the liver, and in relapsing fever. It is a prominent event in the natural history of yellow fever, the so-called black vomit in this disease denoting neither more nor less than gastrorrhagia. It may occur in profound anæmias and in malaria. It may occur in place of the menses in cases of amenorrhœa. Instances in which gastrorrhagia is vicarious are by no means common; in the majority of the cases in which it follows suppression of the menses it proceeds from disease of the stomach; yet that it may take the place of the menses must be admitted. The cessation of habitual hemorrhage in some other situation, the arrest of purulent discharges of long standing, and the healing of old ulcers have been supposed to stand occasionally in a causative relation to gastrorrhagia, but this supposition does not rest on adequate clinical proof. Hemorrhage sometimes occurs from the stomach, as from the bronchial tubes, the Schneiderian membrane, and other situations, without any apparent pathological connections, neither following nor preceding any appreciable morbid conditions. It is then to be considered as idiopathic or as constituting an individual affection. Several cases have come under my observation, one of which, with the hemorrhage extremely profuse, I have reported in another work.² Examinations after death have shown the absence of ulceration, erosions, or of any appreciable solution of continuity, and the hemorrhage is then to be attributed to diapedesis. Hemorrhage from the stomach is an occasional event in pregnancy. It may be caused by a contusion received on the epigastrium. Irrespective of its occurrence as a symptom of gastritis, yellow fever, acute yellow atrophy of the liver, purpura hæmorrhagica, and scorbutus, gastrorrhagia occurs oftener in women than in men. It is a rare event in new-born children, occurring a few hours after birth, the blood being vomited and also passed from the bowels (*mœna neonatorum*). It proves fatal in some of these cases.

The PROGNOSIS in cases of gastrorrhagia will depend upon its pathological import. The prognosis is of course unfavorable if it be associated with gastric

¹ Vide p. 181.

² Vide *Clinical Medicine*, p. 253.

carcinoma or yellow atrophy or cirrhosis of the liver, although under these circumstances death is rarely an immediate effect of the loss of blood. If, however, the hemorrhage be vicarious or not connected with any appreciable morbid conditions, the prognosis, as a rule, is favorable. The loss of blood in proportion as it is considerable or large induces debility, anæmia, and may prove the direct cause of death. The amount and rapidity of the hemorrhage may be such as to induce sudden death from syncope. On the other hand, a vicarious hemorrhage if moderate is not only without danger, but may conduce to the welfare of the system so long as the menstrual discharge remains suppressed. In determining the amount of hemorrhage it is to be borne in mind that the quantity of blood vomited is not always a criterion. The blood may accumulate and coagulate within the stomach without being vomited. The hemorrhage may be sufficient to destroy life, although the quantity vomited be not large. Death may take place in such cases as in cases of concealed uterine hemorrhage after labor. Evidence of hemorrhage being out of proportion to the amount of blood vomited is afforded by dulness on percussion over the distended stomach and symptoms denoting loss of blood—namely, feebleness of the pulse, coldness of the surface, pallor, faintness, etc. The blood thus accumulating within the stomach if not vomited passes into the intestines and is discharged by stool (melæna). Hemorrhage into the stomach has been known to occur and death to take place from the loss of blood without any vomiting.

The TREATMENT of gastrorrhagia has been already referred to in connection with gastric ulcer. The general principles of treatment, having reference to the arrest of hemorrhage and the prevention of its recurrence, are the same under whatever circumstances it occurs. With reference to these objects perfect rest of body and mind is important. If the hemorrhage be profuse or if it recur, rest of the stomach should be secured by withholding from this organ all nutriment and nourishing the patient exclusively by rectal alimentation. Alcoholics if indicated are to be given hypodermically or *per enema*. Opium is useful by quieting the peristaltic movements of the stomach. It should be given hypodermically. The direct refrigerant effect of iced water taken in small quantities at a time, or of swallowing small pieces of ice, is useful. In urgent cases, as a means of arresting the hemorrhage, ice may be applied to the epigastrium. In less urgent cases revulsive measures may be relied upon—namely, sinapisms and dry cups applied in different situations over the abdomen. Hot, stimulating foot-baths are useful by way of revulsion. Hæmostatic remedies, such as ergot, the acetate of lead, tannic acid, etc., if introduced into the stomach, are liable to excite vomiting and thereby do harm. Ergotin may be given by hypodermic injection. Purgatives are contraindicated.

Experience has shown that transfusion is likely to cause renewed hemorrhage, so that this procedure should be resorted to in gastrorrhagia only when there is imminent danger of a fatal termination from the loss of blood; and then only a small quantity should be transfused. The infusion of physiological salt solution is safer than the transfusion of blood, and is about as effective.

These measures are to be employed in individual cases according to the urgency with which the arrest or the prevention of hemorrhage is indicated. If there be ground for regarding the hemorrhage as vicarious, interference will be required only to keep it within proper limits. This statement will also apply to hemorrhage occurring in pregnancy.

The treatment in most cases of gastrorrhagia of course embraces other measures than those having reference to the arrest and the prevention of the hemorrhage—namely, measures addressed to the morbid conditions with

which the hemorrhage is associated. The latter are considered under other heads. So also measures called for after the occurrence of gastric hemorrhage, having reference to debility and anæmia dependent on the loss of blood, need not be here considered. After a considerable hemorrhage the stomach, assuming the non-existence of cancer or ulcer, is enfeebled, and the liability to a recurrence of the hemorrhage is to be kept in view. Careful regulation of the diet, quietude of the body, and the avoidance of all disturbing agencies are important during convalescence. Although profuse or repeated hemorrhages involve more or less immediate danger, patients may recover even when the loss of blood occasions prolonged syncope and extreme anæmia. Striking illustrations of this fact have come under my observation.

Gastric hemorrhage is sometimes simulated by hysterical females and by malingerers among soldiers and prisoners. Blood obtained from animals, and even human blood, may be taken into the stomach, and vomiting excited by various means. This deception may be suspected in the case of a young woman who manifests a morbid disposition to impose on the credulity of those around her as regards her ailments, when the symptoms do not denote loss of blood, when there are no grounds, aside from hemorrhage, to suspect gastric ulcer, and when the menses are not suppressed. Among soldiers and prisoners it is to be suspected when the usual effects of hemorrhage are not apparent, and when the morbid conditions with which gastric hemorrhage is usually associated are wanting. The microscope may be of use in the detection of this kind of deception. Bennett cites a case in which a specimen of blood which it was pretended had been vomited was found to present the characteristic red corpuscles of the blood of a bird.

Leube mentions, as an occasional sequel of gastrorrhagia, double and permanent amaurosis, pallor of the papilla and attenuation of the retinal arteries being the only appearances revealed by the ophthalmoscope. That the amaurosis is simply an effect of anæmia is disproved by the fact that it persists after the anæmic condition disappears. He therefore infers the existence of some connection between the nerves and vessels of the stomach and certain parts of the brain—an inference sustained by the occurrence of gastric hemorrhage after injuries to certain parts of the brain.

Inanition.

In connection with the functional affections of the stomach, I shall offer a few remarks on a pathological condition which is not perhaps entitled to rank in the nosological catalogue as an individual disease, but which is an element of all diseases compromising alimentation and digestion. The pathological condition referred to is *inanition*. The importance of a due appreciation of this condition in medical practice renders it desirable to devote to it some attention, and it may with propriety be noticed in connection with the functional affections of the alimentary canal.

Health requires the assimilation of nutriment adequate in quantity and kind to the wants of nutrition. Every one is familiar with the mental and physical exhaustion felt when abstinence is protracted for only a few hours after the sense of hunger indicates the need of food. Every one knows that the deprivation of aliment for a period varying according to circumstances proves fatal. During the progress of starvation the body loses rapidly in weight, the fat disappears, the muscles diminish in size, exhaustion progressively increases, the heat of the body is lowered, vomiting and diarrhœa not infrequently occur, the mental powers are weakened, listlessness and hebe-

tude are sometimes followed by delirium and coma, and, according to Chossat, if the deprivation of aliment be complete death takes place when one-fourth of the weight of the body at the time aliment was withheld has been lost. The mode of dying is a type of slow asthenia. It is worthy of note that during the progress of starvation hunger is not usually a prominent symptom. If felt for a time it is liable to disappear, and it may be followed by a loathing of food.

Inanition is a pathological condition entering into all diseases which interfere with the ingestion or the assimilation of aliment. The phenomena of inanition in cases of these diseases are combined with the symptoms belonging to the particular disease which exists. The inability of the system to support, resist, and overcome disease proceeds, in a greater or less degree, from this element. The immediate cause of death in many cases of disease proving fatal by slow asthenia is inanition; that is to say, starvation. These are facts of great practical importance, and they are not sufficiently appreciated by many practitioners of medicine.

An important practical bearing of these facts relates to alimentation in the management of diseases. Until recently for many years not only was the importance of alimentation not fully recognized in medical practice, but the dietetic treatment of most diseases contributed to inanition. The writings of Graves led to the employment of alimentation in fevers. It is not less important in all other diseases which tend to destroy life by asthenia. Patients may be starved to death in other diseases as well as in fevers. As a practical rule, it is an object in any disease in which the danger lies in the direction of asthenia to meet, as far as practicable by alimentary supplies, the wants of nutrition. Harm may arise from the ingestion of food beyond the powers of digestion, but no harm can arise from an undue assimilation of food; on the contrary, the greater the assimilation the less the danger from inanition superadded to the disease. Let it be borne in mind that in all diseases tending to destroy life by asthenia there is danger from inanition, but never from hypernutrition! In the language of Chossat, "Inanition is a cause of death which marches silently in front with every disease in which alimentation falls below the normal standard. It reaches its natural termination sometimes sooner and sometimes later than the disease which it covertly accompanies, and it may supersede the disease of which at first it was merely an incidental element."

Alimentation is important in diseases not attended with immediate danger. In proportion as the assimilation of food can be made to approximate to the normal standard, the phenomena of inanition are forestalled, the vital powers are better enabled to tolerate and overcome the disease, the duration of the disease may be shortened, convalescence is hastened, and the recovery is more likely to be complete. As regards the selection of food and the modes of its preparation in different diseases, in addition to dietetic rules based on general experience, our knowledge of alimentary principles, etc., reliance may be placed upon the desires and tastes of the patient; but the absence of appetite is not to be a guide as regards alimentation. Loss of appetite is one of the symptoms of inanition. The wants of the system are not in disease, as in health, always expressed by hunger. The state of the mind dependent on the morbid condition of the nervous system, the coatings on the tongue, etc., interfere with the desire for food and the sense of taste. The practitioner is to exercise his judgment and tact in securing, as far as practicable, the assimilation of an adequate amount of nutriment, either with or without the co-operation of desire and taste on the part of the patient, and it is often better to incur risk of exceeding rather than falling below the quantity of food which the wants of the system seem to require. It may be laid down as a principle

applicable to the management of most acute diseases that the assimilation of food to the fullest practicable extent is important; and it is a maxim of conservative medicine that under all circumstances a chronic affection is less likely to be prolonged, serious lesions of structure are less liable to take place, and a fatal termination is postponed, in proportion as the vital powers are maintained by a nutritious diet.¹

Innutrition is not infrequently involved in the causation of diseases. The connection between scarcity of food and the prevalence of typhus has been repeatedly observed in epidemics in Ireland. The same connection in individual cases and families is observed frequently everywhere. Scorbutus is caused by a deficiency of certain alimentary principles or the want of a sufficient variety in food. Insufficient nourishment, which is sometimes involuntary and sometimes voluntary, is supposed to favor the development of phthisis in persons having the tuberculous predisposition. This cause may co-operate with other causes in giving rise to various diseases, whether epidemic or sporadic; and the ability of the system to bear up under disease is impaired in proportion as the powers of life are enfeebled by previous defective alimentation.

Want of success in the treatment of diseases in hospitals, and often in private practice, especially among the poorer classes, is attributable in no small measure to the want of adequate alimentation.

CHAPTER V.

INFLAMMATORY DISEASES OF THE INTESTINE.

Anatomical Characters of Acute Dysentery.—Sporadic Dysentery.—Epidemic Dysentery.—Chronic Dysentery.—Inflammation and Perforation of the Cæcum.—Fecal Abscess.—Inflammation and Perforation of the Vermiform Appendix.—Colitis.—Proctitis.—Acute Enteritis.—Subacute and Chronic Enteritis.

Acute Dysentery.

THE term dysentery has long been in use to designate an inflammatory disease of the large intestine characterized by mucous and bloody dejections and by tenesmus. As a name for the disease it is not very distinctive, its etymology simply expressing intestinal difficulty; but it is not easy to substitute a term conformable to the nomenclature of inflammatory affections, as there is no anatomical name for the large intestine as a whole. The term dysentery has the advantage of not expressing anything erroneous or doubtful in regard to the pathological character of the disease. Acute and chronic dysentery claim separate consideration. Acute dysentery occurs as a sporadic and as an epidemic disease. This is a distinction of much clinical importance. After having considered the anatomical characters of sporadic and epidemic dysentery, these two forms of the disease will be treated of separately as regards clinical history, pathological character, etc.

¹Vide "Essays on Conservative Medicine," by the author, *American Journal of the Medical Sciences*, January and October, 1863. Vide, also, essay on "Alimentation in Disease," *New York Med. Journal*, 1867, and the work entitled *Essays on Conservative Medicine and Kindred Topics*.

ANATOMICAL CHARACTERS.—After death from acute dysentery the mucous membrane of the large intestine is in a condition either of simple mucopurulent or of diphtheritic inflammation. Anatomically, therefore, the disease is distinguished as simple inflammatory—or, as it is also called in accordance with German nomenclature, catarrhal dysentery—and as diphtheritic dysentery. Most of the cases of sporadic dysentery are of the simple inflammatory variety which is the milder of the two varieties. The largest number of cases of diphtheritic dysentery belong to the epidemic form of the disease. The anatomical, however, cannot be used interchangeably with the clinical terms. Diphtheritic dysentery may occur sporadically, and epidemic dysentery usually includes a large number of cases of the simple inflammatory variety. There are, moreover, all grades of transition between the mildest cases of simple inflammatory dysentery and the most malignant cases of diphtheritic dysentery. It is not always possible during life to distinguish between simple and diphtheritic inflammation of the large intestine. For these and other reasons it is most convenient to treat of the clinical history of acute dysentery under the headings Sporadic and Epidemic Dysentery, but to describe the anatomical appearances first of simple and then of diphtheritic inflammation of the large intestine.

Dysentery in the *acute simple* (catarrhal) variety is a simple inflammation of the inner coats of the large intestine. The inflammatory process is usually more intense in certain situations than in others. The parts most involved are the cæcum, the hepatic and the splenic flexures of the colon, the sigmoid flexure and the rectum. These are the parts where the contents of the large intestine remain longest in contact with the mucous membrane. The inflammation often, although not invariably, increases in degree toward the lower end of the large intestine. The lower part of the ileum is also frequently involved in the inflammatory process.

The mucous membrane is reddened, softened, and swollen. The redness is usually in patches, and is most intense in the situations named. The color varies from light pink to dark, livid red. The redness is due chiefly to hyperæmia, as is evident from the arborescent appearance, especially marked when the intestine is examined by transmitted light. In addition to congestion, however, there are usually extravasations of blood in the mucous and submucous tissues in the form either of punctate or of diffuse ecchymoses. It may happen that a congested appearance is not evident after death, as may be the case in inflammation of other mucous membranes. The surface of the mucous membrane is covered with a layer of tenacious mucus, either colorless or of a yellowish or brownish-red hue from admixture of bile and blood. Sometimes the admixture of pus is sufficient to give an opaque, yellowish color to the mucus. The mucus contains, microscopically, pus-cells, red blood-corpuscles, and desquamated epithelial cells. Both the mucous membrane and the submucous tissue are swollen, the latter often in the greater degree. This swelling is due to congestion, together with the exudation of serum and of pus-cells. The solitary follicles are usually swollen, and they appear as grayish-white projections about the size of a pin's head, surrounded by a zone of congestion. They may become as large as a small pea. Sometimes the inflammation seems to be chiefly in the follicles. The disease is then sometimes called *follicular dysentery*. If there have been repeated attacks of acute dysentery, or if the acute passes into a chronic stage, the mucous membrane becomes more or less pigmented. Points of dark pigment appear in the centre of the solitary and of the agminated follicles. In Peyer's patches this pigmentation gives rise to the so-called shaven-beard appearance. The pigment is chiefly in the form of brown granules in the lymphoid cells. Diffuse patches and streaks of slate-colored or brownish pigmentation may

appear outside of the follicles in the mucous membrane, especially in the large intestine. Small follicular ulcers, due to softening and breaking down of the follicles, are often observed in acute dysentery, especially in the follicular variety. The peritoneum over the parts most inflamed may be normal or it may be coated with a layer of fibrin.

Microscopical examination shows the small veins and capillaries of the mucous membrane and of the submucous tissue, particularly of its upper layers, distended with blood. In some places there may be only hyperæmia, but as a rule there is distinct evidence of inflammation. This is afforded by the presence of pus-cells. The pus-cells are particularly abundant near the *muscularis mucosæ* (Brücke's muscle), just below the glands of Lieberkühn, where there is normally a rich network of blood-vessels. The pus-cells are frequently observed in swarms around the small veins. There are also pus-cells in the mucous membrane between the glands of Lieberkühn; but as the connective tissue in this situation is of the variety called adenoid, which normally is densely infiltrated with lymphoid cells, it is difficult to determine here the presence of a moderate number of pus-cells, as these anatomically resemble the lymphoid cells. If the pus-cells accumulate in large number, they press apart and distort the glands of Lieberkühn. The enlargement of the solitary follicles is due to an increase in the number of lymphoid elements. These infiltrate the surrounding submucous tissue. In addition to the emigration of white corpuscles more or less red corpuscles escape by diapedesis. The larger hemorrhages are the result of rupture of the vessel-walls (rhexis). The spaces between the fibres of the submucous tissue are distended by the presence of serum (œdema). As already said, the accumulation of lymphoid cells may be sufficient to compress the tubules of Lieberkühn. In this way the tubules may be obstructed in certain parts. They may undergo cystic dilatation below the seat of obstruction. Most of the epithelial cells lining the tubules are distended with mucus, and they appear as so-called goblet or caliciform cells—forms which are normally very frequent in the large intestine. The fate of the columnar epithelium covering the inner surface of the mucous membrane is uncertain. As under normal circumstances this epithelium soon desquamates after death, its absence from its normal place in inflammation cannot be considered evidence of its separation during life. It is not probable that extensive desquamation of the epithelium occurs during life.

The description which has been given of the histological changes in acute simple inflammation of the intestine in dysentery is applicable to the same variety of inflammation in other conditions, as in acute enteritis. It is especially the involvement of the lower part of the large intestine in the inflammatory process which characterizes acute dysentery. As is evident from the description, there are no changes in acute simple dysentery which may not undergo resolution, with the exception of the follicular ulcerations, which are by no means always present, and which may readily cicatrize. More or less pigmentation and atrophy of the mucous membrane usually remains after an attack of dysentery.

Some writers describe a more severe form of purulent inflammation than that to which the name simple inflammatory dysentery has been given. In this, excessive suppuration occurs and ulcers are formed by destruction of the superficial layers of the mucous membrane. Follicular ulcers are present at the same time.

Dysentery with *diphtheritic* or *pseudo-membranous exudation* is a much graver disease than the simple inflammatory variety. It is called diphtheritic, not on account of any connection with diphtheria of the pharynx, but in consequence of the resemblance between its lesions and those of diphtheritic

inflammation of the throat. It is also called fibrinous (croupous) dysentery, and corresponds in its more severe manifestations to the putrid and gangrenous dysentery of the old writers. Diphtheritic inflammation of the large intestine is characterized by the presence of an exudation containing fibrin, blood, and pus-cells upon the surface and in the substance of the mucous membrane, combined with sloughing and consequent loss of substance of the mucous membrane. A large number of cases of epidemic dysentery are of this type, but it may also occur sporadically.

According to Virchow, diphtheritic dysentery is always preceded by simple inflammation of the large intestine. Others believe that the inflammation may be diphtheritic from the onset. However this may be, diphtheritic inflammation is very frequently combined with simple inflammation. The morbid changes are usually, as in simple inflammation, most marked in the cæcum, the flexures, and the rectum, and they affect by preference the projecting folds of the mucous membrane. The inflammation is often most intense in the sigmoid flexure and the rectum, and it may be confined to these parts. Sometimes the rectum escapes. In other cases the inflammation is uninterrupted from the beginning to the end of the large intestine. In the lower part of the ileum simple inflammation is frequently present, but there is rarely diphtheritic inflammation. In the early stages of the diphtheritic process the inner surface of the large intestine presents here and there patches of grayish-red, yellow, or variously discolored material, of varying thickness and extent, usually soft, but sometimes firm. This pseudo-membranous deposit consists of an exudation of fibrin, pus, and blood involving the upper layers of the mucous membrane. It extends in depth and destroys the vitality of the invaded tissue. The mucous membrane and often the subjacent tissues slough. In this way the so-called diphtheritic ulcers are produced, which may extend only in part through the mucous membrane, or they may expose the submucous tissue and even the muscular coat of the intestine. By further extension of the sloughing process the wall of the intestine may be perforated and a fatal peritonitis induced. This occurrence is infrequent. The diphtheritic ulcers are irregular in shape, their walls being bevelled or abrupt, in some cases overhanging. Sometimes little openings appear in the bed of the ulcer, which lead into dilated tubules of Lieberkühn. The ulcers may be so extensive that the undestroyed mucous membrane appears in the form of scattered islands rising from the surrounding depressions. The mucous membrane may slough away in little shreds or in larger coherent masses, sometimes several inches in extent. In advanced cases the inner surface of the intestine—with the ulcerations, the pseudo-membranous deposits, the ridges of mucous membrane, the partially detached sloughs, all of various colors and consistence—presents a peculiarly variegated appearance. Enlargement of the follicles and follicular ulcerations may likewise be present. The submucous tissue, where preserved, is usually much swollen and infiltrated with blood and pus. Submucous abscesses may form and undermine the mucous membrane. The peritoneal covering of the inflamed portion of the intestine is congested and is frequently coated with fibrin. Thus, circumscribed and sometimes general peritonitis may occur, agglutinating the coils of intestine.

The microscopical examination shows sometimes distinctly fibrillated fibrin, enclosing red blood-corpuscles, pus, and epithelial cells, as a firm layer upon the surface of the mucous membrane, extending into the glands of Lieberkühn and infiltrating the substance of the mucous membrane. Frequently, however, the pultaceous deposits on the inner surface of the intestine present little evidence of structure, but consist of a mass of granular material, low vegetable organisms, and decomposed blood. In the sloughs of mucous membrane careful inspection may reveal traces of the glands of Lieberkühn. These

glands, when preserved, often present constrictions and cystic dilatations. These cysts may invade the solitary follicles. In the submucous layer a network of fibrin appears in the dilated interstices of the connective tissue, especially in the lymphatic vessels. Hemorrhages and pus-cells are abundant. Bacteria are frequently observed in the coats of the intestine and in the pseudo-membranous deposits. It is difficult to assign to these and the other forms of low organisms observed here any pathological significance, as they are normally present in large number in the feces, and as decomposition rapidly attacks the sloughy masses in dysentery. Coagulation necrosis is probably an essential element in the pathology of diphtheritic dysentery, as of fibrinous inflammations of mucous membranes in general.

When the sloughing process involves the mucous membrane of most of the large intestine death is almost inevitable. Less extensive diphtheritic ulcerations may cicatrize. Granulation-tissue develops from the surface of the ulcer. The cicatrix is composed of dense fibrous tissue, covered with epithelium but without glandular elements. The cicatrix is usually puckered, and it causes some contraction of the surrounding tissue. Sometimes, but not frequently, stricture of the intestine, followed by grave and even fatal symptoms, is produced by the contraction of these cicatrices. The healing of these ulcers is slow and is attended by the symptoms of chronic dysentery.

Of changes in other organs of the body occasionally observed in diphtheritic dysentery, abscess of the liver deserves especial mention. This is a frequent complication in tropical climates. It is not frequent in this climate, but it seems to be oftener observed here than in Great Britain and on the continent of Europe. The abscesses are usually multiple. They are explained by the transportation of infectious emboli derived from thrombi in the mesenteric veins proceeding from the diseased intestine. The mesenteric glands are usually swollen, and they may suppurate. Pulmonary complications, such as pneumonitis and œdema, are frequent. Parenchymatous degeneration of the kidney and occasionally acute diffuse nephritis occur.¹

The foregoing account of the anatomical characters is of course descriptive of appearances observed in fatal cases of sporadic and epidemic dysentery. It is to be added that in either form the disease is not infrequently so mild as to involve no danger, and hence in mild cases the opportunity of inspecting the parts after death is not offered. There are but few diseases in the nosology which offer a wider contrast than the mildest cases of sporadic and the gravest cases of epidemic dysentery.

Sporadic Dysentery.

CLINICAL HISTORY.—Dysentery is generally preceded by simple diarrhœa; that is, more or less frequent and loose dejections of a feculent character. Of 33 recorded cases which I have analyzed with reference to this point, these dejections preceded the characteristic dysenteric evacuations in 30. The latter appeared after the former had existed for a period varying from twenty-four hours to seven days.² With this prodromic diarrhœa there are colic pains, the appetite is impaired, and there is a general feeling of malaise. A pronounced chill rarely occurs, and even chilly sensations are not common.

The various ingredients which may enter into the composition of dysenteric

¹ An exhaustive consideration of the pathology and of other subjects pertaining to the natural history of diarrhœa and dysentery is given by Woodward in the second medical volume of the *Medical and Surgical History of the War of the Rebellion*, Washington, 1879.

² *Clinical Report on Dysentery*, based on an analysis of 49 cases, by the author, 1853.

stools are—feculent matter, mucus, blood, pus, serum, pseudo-membranes, necrotic tissue, bacteria together with other low organisms, and undigested aliment. According to the preponderance of one or more of these substances the stools are described as mucous, muco-purulent, muco-sanguineous, sero-sanguineous, sanguineo-purulent, gangrenous, bloody, or purulent. The presence of pseudo-membranes and of necrotic portions of the intestinal coats is characteristic of the diphtheritic form of inflammation. The other ingredients are common to both varieties of inflammation. The development of the disease is denoted by characteristic evacuations consisting of mucus, with which more or less blood is usually commingled. The quantity passed at each act of defecation is generally small, but the act is repeated at short intervals, slight evacuations often taking place every hour or two, and sometimes a few moments only intervening. The mucus is discharged in the form of clumps of a yellowish or reddish glairy material, sometimes without feces and sometimes around balls of feces. The quantity of mucus expelled in some cases is abundant, and forms a jelly-like mass not unlike a collection of the rusty sputa of pneumonia. Microscopical examination of the mucous discharges shows cells resembling the white blood-corpuscles (called often, in this situation, mucous corpuscles, but in no way differing from pus-cells), red blood-corpuscles, bacteria, and sometimes cylindrical and flattened epithelial cells. The mucus itself is characterized by its viscid nature, and by its precipitation with acetic acid in the form of threads and flakes of mucin insoluble in an excess of the acid. When the mucous or pus-corpuscles are present in large number the substance acquires an opaque whitish or yellow appearance, and is called muco-pus. The blood may give a diffuse or a streaky red color to the discharges. After the characteristic dysenteric stools appear, feculent matters are usually entirely absent. These may, however, appear, at intervals, especially in the form of hard balls of feces called scybala. When improvement begins feculent matters appear in the stools. In mild cases the discharges may remain mucous throughout the whole course of the disease. In severe cases of sporadic (and frequently in epidemic) dysentery the discharge of a sero-sanguinolent liquid occurs. The serous fluid is very rich in albumen, of which large quantities may be precipitated, after filtration, by nitric acid. The amount of albumen is much greater than can be accounted for by the admixture of blood. It is the result of exudation of the blood-plasma. The characteristic stools of diphtheritic inflammation of the large intestine consist of a sero-sanguineous fluid containing small morsels of pseudo-membranous and necrotic tissue. These morsels have been compared to raw minced meat, and the yellowish-red fluid containing them was called by the older writers *lotura carniūm*. The microscopical examination of these shreds and particles frequently shows only a mass of decomposing granular matter and bacteria mingled with blood-corpuscles and perhaps indistinctly fibrillated fibrin. In other specimens the fibrin may be more distinct. The examination of a sufficient number of specimens will usually bring to view some in which fragments of the tubules of Lieberkühn can be recognized, and thus is demonstrated the origin of these particles from necrosed intestinal mucous membrane. These stools emit a peculiarly offensive, cadaveric odor. Less frequent than the presence of these small shreds is the discharge of large fragments of necrosed mucous membrane. These may be several inches in length. The stools containing them are dark in color, have a putrid odor, and are called gangrenous. The tubular pseudo-membranous casts which have been described by some writers are composed of inspissated mucus. They are very rarely observed in dysentery, but are present in a rare form of enteritis called membranous enteritis, muco-colitis, or tubular diarrhoea. Bacteria are present in dysenteric stools in enormous number. Fungus-spores and infusoria are also observed.

The stools may consist almost wholly of blood or they may be chiefly purulent. Little transparent clumps resembling granules of boiled sago or frogs' spawn have been seen in dysenteric stools. According to many writers, they consist of masses of mucus moulded into a round form in follicular ulcers. According to Virchow, they are colored blue with iodine, and are, in reality, undigested granules of starch. Woodward also considers them to be of a starchy nature. Dysenteric stools are usually alkaline in reaction, and are said to contain carbonate of ammonia.

The inflammation of the rectum occasions a sensation as if this portion of the bowel were filled, and leads to the frequent desire to defecate, with as much straining as the soreness of the parts will allow. This disposition to strain ineffectually is called *tenesmus*. Sometimes the straining efforts produce prolapsus of the intestine. The evacuations are frequently preceded by griping or colic pains which are called *tormina*. The tormina and tenesmus are not proportionate to the gravity of the disease. They are sometimes wanting in fatal cases, and are prominent symptoms in some mild cases. They are, however, the chief sources of suffering. Tenderness on pressure is in some cases more or less marked over the descending colon and sometimes over the whole tract of the large intestine. It is rarely great, and not infrequently is wanting. Meteorism or tympanitic distension is rarely present. The abdomen is usually depressed. Strangury and retention of urine are occasional symptoms, and in the female leucorrhœa may be produced. Redness and excoriation around the anus may be produced by the irritation of the dejections. Perineal abscess is an occasional result of an extension of the inflammation. Intussusception, with the symptoms of ileus, sometimes occurs in children.

The pulse in the majority of cases is but little, and sometimes not at all, accelerated. The body-heat is but moderately or slightly increased. Exceptionally, high febrile movement exists. The thermometer may show an increase of temperature to 103° or 104°. Great frequency of the pulse always denotes gravity and danger, but the converse does not hold good. In some fatal cases the pulse is never much accelerated. The tongue may be frosted or more or less coated, or it may present a natural appearance. During the course of the disease the appetite is sometimes more or less diminished or is lost. Thirst is usually present, and is sometimes urgent. Vomiting occasionally occurs, and may be prominent as a symptom, the matter vomited being of a greenish color. The intellect is unaffected, as a rule, delirium occurring with great infrequency in cases which end in recovery, but occasionally, in cases which prove fatal, being present toward the close of life. The loss of strength varies greatly in different cases according to the intensity and extent of the local affection, depending also on the condition of the patient when attacked.

The duration of the disease from the date of the attack to convalescence varies from four to twenty-one days. These figures represent the minimum and maximum duration in thirty recorded cases.

PATHOLOGICAL CHARACTER.—Our present knowledge of the pathology of sporadic dysentery embraces only the intestinal affection, the local and general phenomena which make up the clinical history being symptomatic of this affection. The pathological character of the intestinal affection is the same in the sporadic as in the epidemic form of the disease.

Writers have described different varieties of the disease, distinguished as typhoid, bilious, intermittent and remittent, febrile and non-febrile, etc. These terms denote either variations in the phenomena of the disease or the coexistence of other diseases. Dysentery may occur as a complication of continued and of periodical fever. Rheumatism and dysentery are occasionally

associated. These combinations are important in their practical relations, but it does not follow that the disease under these circumstances is specifically different from its ordinary form. Variations as regards febrile movement, supposed disorder of the liver, etc. do not affect the special character of the disease. Paralysis affecting certain muscles, especially the muscles of the lower limbs (paraplegia), has been observed in some cases to either accompany or follow dysentery; and different theories have been proposed to explain a supposed pathological connection between the paralytic and the dysenteric affection. The truth is, the affections are so rarely connected that their association is probably a mere coincidence.

CAUSATION.—No age is exempt from liability to this disease, but in the majority of cases the patients are adults and less than thirty-five years of age. A larger number of males than females are attacked, but the preponderance is not sufficient to show that a marked predisposition relates to sex. The causation has a very obvious relation to climate. The disease is much more frequent, in the sporadic as well as in the epidemic form, in tropical than in cold and temperate climates. The causation has also a striking relation to season. Of 44 cases which I recorded, all save 1 case occurred in July, August, September, and October. The constitution and previous health were good in one-half of the cases which I have analyzed, and in the remaining half there was no uniformity in character as regards the antecedent affections or disordered health.

Writers have been accustomed to state that the disease may be produced by various obvious causes, such as atmospherical changes, excess in eating and drinking, indulgence in acid, unripe fruits, crude vegetables, etc.; but in the majority of cases its origin cannot be traced to these causes or to any obvious cause. This renders it probable that a special cause is involved in sporadic as well as in epidemic dysentery. The limitation of the occurrence of the disease to the summer and autumnal season, and its more frequent occurrence in tropical climates, point to this conclusion and to the agency of a high temperature in the evolution of the special cause. Persons who are in good health and vigorous are as likely to be affected as those who are feeble. Various circumstances standing in a causative relation to the disease in an epidemic form may also be involved in its production when it is sporadic. These causative circumstances will be noticed in treating of epidemic dysentery. [Numerous attempts have been made to establish a causative relation between certain organisms found in the large intestine and dysentery, but with one exception they have thus far been unsuccessful. In 1859, Lambl of Prague observed an association between an amœbic organism and dysenteric inflammation. This observation was confirmed in 1875 by Lösch of St. Petersburg, who gave the organism the name of *amœba coli*. The most extensive investigations of the subject of "amœbic dysentery" have been made by Kartulis of Alexandria, Egypt, who found the amœbæ in more than five hundred cases of tropical dysentery, and never in any other form of diarrhœa. On the other hand, Lewis and Cunningham have found amœbiform organisms in the discharges of cholera, in those of diarrhœa, and even in the healthy intestine. Osler was the first in America to detect the amœba coli in the evacuations of a dysenteric patient and in the pus of an hepatic abscess with which the case was complicated. Numerous cases of "amœbic dysentery" have been since reported by Councilman and Lafleur, Stengel,¹ Dock, Musser, and others.

The weight of present opinion is undoubtedly in favor of the view that

¹Stengel's observations were made in cases in the writer's wards at the Philadelphia Hospital in the autumn of 1890.

there is a distinct form of dysentery dependent upon the presence of the *amœba coli*.

Councilman thinks it possible that the *bacillus coli communis* may be concerned in the production of so-called secondary dysentery—i. e. dysentery occurring in late stages of exhausting chronic diseases.¹—H.]

DIAGNOSIS.—The diagnosis of dysentery involves no difficulty. The characteristic evacuations are pathognomonic. It is to be discriminated from cases of bloody evacuations and irritation of the rectum incident to hemorrhoids, intestinal hemorrhage or melæna, and the discharge of pus from an abscess opening into the intestine. The points of contrast with dysentery which these cases offer are sufficiently apparent. [A search should be made in all cases for the *amœba coli*.—H.]

PROGNOSIS.—Sporadic dysentery in temperate climates tends to recovery. It is a distressing disease, but is attended with little danger to life. A fatal result is due either to an unusual intensity and extent of the local affection, to an inability of the system to resist the disease from feebleness of constitution, or to some coexisting affection. The prognosis in tropical climates is less favorable. The recovery from the disease in temperate climates is almost always complete; that is, it rarely eventuates in chronic dysentery; nor does it predispose to any other disease. In tropical climates abscess of the liver is not an infrequent sequel. This very rarely follows in temperate climates. So far as my experience goes, immediate relapses are not likely to take place, and the occurrence of the disease diminishes the liability to its occurrence at a subsequent period. With reference to the latter point, my analysis of cases, although the number was not large, developed an interesting result. Of the cases recorded during fourteen years, in not a single instance was the disease known to recur; and in 16 of these cases the patients were under observation after recovery during periods varying from one year to thirteen years. This result was the more striking from the fact that the patients for several years were within the sphere of an epidemic influence which in some instances affected other members of the same families.

TREATMENT.—Sporadic dysentery is a self-limited disease, and in the great majority of cases would end in recovery without medicinal treatment. In order to study its natural history I allowed the disease in 10 cases to pass through its course without any therapeutical interference. These were sporadic cases of average severity. They ended in recovery after an average duration of from eight to nine days. An analysis of 49 cases previously recorded, in which different methods of treatment were employed, gave about the same duration in the cases ending in recovery.² These observations are sufficient to establish the self-limitation of sporadic dysentery and its intrinsic tendency to recovery—facts which, so far as I know, had not been before demonstrated by withholding all medication in a series of cases; but there is reason to believe that the disease is sometimes arrested, that its duration may be frequently abridged, and that the distressing symptoms may be greatly relieved by judicious therapeutical measures.

It is desirable that as early as possible the fecal contents of the large intestine should be effectually removed, in order to prevent their continued passage over the inflamed surface, and to secure so far as may be that import-

¹ *Trans. Association of American Physicians*, vol. vii. p. 122.

² Vide "A Contribution toward the Natural History of Acute Dysentery," in the *Am. Journ. of Med. Sciences*, July, 1875, and a clinical report based on analyses of 49 cases, in the *Buffalo Med. Journ.*, July, Aug., Sept., and Oct., 1853.

ant end in the treatment of all inflammations—namely, rest of the inflamed part. It would seem that nature endeavors to relieve the bowels of their contents by the diarrhœa which precedes the dysenteric evacuations. The first point in entering on the treatment is to ascertain if the bowels have been spontaneously relieved. With reference to this point the size and character of the stools are to be ascertained and the abdomen examined by palpation. In general, it is advisable to render the effort of nature more complete by giving an effective purgative. Castor oil has been in much repute as an appropriate remedy, but, aside from the objection on the score of the disgust which many persons have for this remedy, the saline cathartics are to be preferred. The sulphate of magnesia or soda, the Rochelle salts, or the citrate of magnesia may be employed. The saline selected should be given in sufficient doses to promptly produce abundant dejections, and it is then to be discontinued. It will sometimes happen that after free purgation the dysenteric evacuations do not return and recovery at once ensues. This abortive effect takes place only in some cases in which the inflammation is not intense and is limited in its extent. Notable diminution of the frequency of the dysenteric evacuations and relief of the tormina and the tenesmus not infrequently follow the operation of the saline purgative. This treatment may be pursued except in cases in which it is contraindicated by great feebleness of the patient. In these cases castor oil is the purgative to be preferred.

Another method of effecting the removal of the contents of the large intestine deserves mention—namely, the employment of large injections. More than a century ago O'Beirne demonstrated that a flexible tube can be passed into the sigmoid flexure, and in this way a large quantity of liquid injected into the colon. He advocated the employment of this method in dysentery and other affections. Under the name irrigation (*Darmeingiessungen*) this method has been recently revived, and it is recommended on the basis of clinical experience especially by two German writers, Hegar and Mosler.¹ By means of a tube carried into the sigmoid flexure several quarts of liquid may be injected. By the writers just named the injection is made through a funnel elevated sufficiently for the requisite force from gravitation. The object is to remove fecal accumulations and all irritating matters. By this method also medicated liquids may be brought into contact with the inflamed surface. The method claims trial sufficient to determine whether it can advantageously take the place of saline or other cathartics in the treatment of dysentery, and also to what extent the topical application of medicated liquids may be employed with advantage. The injections may be repeated two or three times daily. They are made more effectual if the patient be placed in the knee-and-elbow or the knee-and-shoulder posture, but if the patient be feeble the decubitus may be on the back or side. Davidson's syringe will probably answer as well as, if not better than, the elevated funnel. In order to introduce as much water as is practicable and desirable, it should be introduced slowly, intermitting the injection for a few moments from time to time.

[The medicated solutions employed with the best results in the treatment of dysentery are those containing corrosive sublimate (1:5000), nitrate of silver (1 or 2 grains to the ounce), boracic acid, and quinine. The last, in the strength of 1:5000 and 1:2500, is believed by Councilman and Lafleur to be particularly efficacious in the treatment of amœbic dysentery, this opinion being based upon the fact, first observed by Lösch, that the amœbæ are killed outside of the body by a quinine solution of the strength of 1:5000. From a pint to a quart of the quinine solution may be injected thrice daily.—H.]

¹ *Deutsches Archiv für klin. Med.*, 1875, Bd. 15, p. 233.

After purgation, opium in some form is the remedy most to be relied upon. A full dose of opium administered by enema or as a suppository will sometimes succeed in arresting the disease. It often mitigates the severity of the disease and affords marked relief. Administered by the rectum, however, it is not always retained, and then reliance must be had upon its administration *per os* or hypodermically. It may be given in full doses repeated every four, six, or eight hours, or in smaller doses repeated at shorter intervals. As regards the form of opium selected, I believe this is chiefly important in respect to the preference or peculiarity of the patient. I have seen the opium in gum or powder, the various liquid preparations, and the salts of morphia equally effectual. The form found to be preferable is to be continued during the progress of the disease, the doses being regulated by the frequency of the evacuations and the suffering. Experience in each case is to be the guide as to the mode of administration. Generally, the administration by the mouth and rectum alternately is advisable. The opiate remedies are to be gradually diminished as the dysenteric evacuations become less frequent and the suffering from tormina and tenesmus is less. After two or three days, if the disease continue, the saline purgative may be repeated, if not contraindicated by the feebleness of the patient, and afterward the use of opium resumed.

In this plan of treatment the reliance is upon free purgation and opium. The chief reliance, I believe, should be upon these measures, but other measures may be conjoined. The subnitrate or the subcarbonate of bismuth in scruple or half-drachm doses, the acetate of lead, the sulphate of copper, gallic acid, and the various vegetable astringents, such as rhatania, kino, catechu, hæmatoxylon, etc., are useful as adjuvants. These are to be relied upon, to the exclusion of opium, in those cases only in which, from a constitutional peculiarity, the latter produces unpleasant effects sufficient to preclude its employment. It is undoubtedly true that some persons are affected so unpleasantly by opium that its use is, if possible, to be avoided; but it is often the case that it is well borne in this and some other diseases, although it may not be in trivial affections. Certain preparations of opium may be well borne, although others occasion unpleasant effects. An aqueous solution or extract is frequently taken without difficulty by those who cannot comfortably take other preparations. Codeia sometimes answers well as a substitute for the preparations of opium and morphia.

Dr. Q. C. Smith of Texas recommends belladonna as an adjunct to opium, and as a substitute when the latter remedy is not well borne. His recommendation is based on a large personal experience and on the testimony of physicians in his neighborhood. He has found belladonna especially useful in cases occurring in childhood, in view of the fact that opium must be given to children with more caution than to adults.

Ipecacuanha has been considered a valuable remedy in dysentery. Some have attributed to it a special curative influence, and have advocated its employment in as large doses as can be borne. Maclean states that the system of treating acute dysentery generally followed in India is as follows: Thirty drops of the tincture of opium may be at first given, but this may be sometimes omitted and the ipecacuanha given at once. If the opiate be given, in half an hour it is to be followed by from 25 to 30 grs. of ipecacuanha. The latter remedy should be given in as small a quantity of fluid as possible, and a little syrup of orange-peel covers the taste of the medicine. The patient after this dose should keep perfectly quiet and abstain from fluid for at least three hours. With these precautions nausea and vomiting are rarely troublesome. After eight or ten hours the ipecacuanha may be repeated in a reduced dose, observing the same precautions.¹ If required,

¹ Vide article on dysentery in *A System of Medicine*, edited by Reynolds.

the treatment is to be continued for several days, the remedy being given in diminished doses, with intervals sufficient to allow mild nourishment to be taken. He cites statistics showing the mortality in India under the use of ipecacuanha to be 28.87 in 1000, whereas under the old system the mortality was 88.2 in 1000. It is to be borne in mind, however, that the old system of treatment included bloodletting and the free use of mercury. I have resorted to this plan of treatment in a considerable number of cases at Bellevue Hospital, but without very satisfactory results. In a small proportion of cases the disease was either arrested or was favorably modified by it, but in the majority of cases it had no apparent influence on the disease.

Mercury has been heretofore much relied upon in the treatment of this disease, given either in large doses, united with opium in order to prevent a cathartic effect, or in small doses repeated at short intervals. The recovery in cases treated with mercury is of course no proof of its value, inasmuch as sporadic dysentery tends intrinsically to recovery. The duration of the disease, the relief of the symptoms, the rapidity of convalescence, and the subsequent condition of health are the points to be considered in estimating the influence of remedies in this disease. With reference to these points a fair estimate of the effects of mercury has led to its rejection by most practitioners in this country as a remedy for dysentery.

During the early part of the disease the diet should be restricted to a small quantity of the blandest articles of food. It is an object throughout the disease to keep the patient on a diet which will leave but little residuary matter to pass into the large intestine; in other words, a diet as purely nutritious as possible. After the first few days, however, it is important to provide for proper support of the system by nutritive supplies, and for this purpose milk and animal broths are best suited. If the symptoms denote failure of the vital powers, alcoholics are to be given, as in all diseases which destroy life by asthenia. Tonic remedies may be given with advantage during convalescence.

Patients should be instructed to refrain as much as possible from repeated acts of defecation and straining efforts. Cold applications to the anus sometimes relieve the tenesmus. A piece of ice may be wrapped in cloth and applied frequently in this situation. Enemas of cold water are often grateful. Relief in some cases is afforded by injecting astringent liquids. The nitrate of silver, a solution of tannin, acetate of lead, or the sulphate of zinc may be thus used.

Fomentations and mild revulsive applications over the abdomen are useful as palliatives in proportion to the amount of tormina and abdominal tenderness.

Epidemic Dysentery.

Epidemic dysentery is essentially the same disease as sporadic dysentery. Certain events occur much oftener in the former than in the latter, yet there is nothing pertaining to the epidemic which is not occasionally seen in the sporadic form of the disease. Epidemic dysentery is often very fatal, yet in the epidemics attended with the largest fatality cases occur which are as mild as the mildest sporadic cases, and on the other hand occasionally in sporadic cases life is quickly destroyed. Like other diseases which prevail epidemically, this differs greatly at different times and places as regards gravity, and at certain times and places it presents features which it does not present at other times and places. The differences between the epidemics of this disease are in a measure to be explained by the coexistence of other diseases,

and by the conjoint operation of morbid causes not standing in a special relation to the production of this affection. In treating of epidemic dysentery the main object will be to point out the circumstances in which it is likely to differ from sporadic dysentery.

With respect to the ANATOMICAL CHARACTERS, they are essentially the same as in cases of sporadic dysentery. In fatal cases of either form the varied appearances which have been stated may be found. Extensive and disorganizing changes occur oftener in epidemic dysentery. As a rule, in the latter the inflammation extends over a larger portion of the large intestine, and it sometimes extends into the ileum. Ulcerations and diphtheritic exudation are much more likely to occur in epidemic dysentery. Perforation of the intestine is sometimes a result of ulceration, giving rise to peritonitis. Perforation of the cæcum may take place in this disease, leading to abscess in the areolar tissue beneath the peritoneum or fecal abscess. Perforation of the rectum and fecal abscess in that situation have been known to occur.

The CLINICAL HISTORY of epidemic differs from that of sporadic dysentery according to differences as regards the extent and severity of the local affection, and also according to various morbid conditions due to the action of accessory causes, the latter co-operating oftener in epidemic than in sporadic cases. Severe cases of epidemic dysentery are characterized by the occurrence of sero-sanguinolent dejections, the *lotura carniū* of the older writers, containing usually pseudo-membranous and necrotic particles in more or less abundance, and holding in solution a large quantity of albumen. Hence epidemics of dysentery are popularly known as *bloody flux*. Dejections of this character always denote gravity of disease. Tormina and tenesmus may be less prominent as symptoms in severe cases of epidemic than in most cases of sporadic dysentery. In some fatal cases these symptoms are entirely wanting. Tenderness over the tract of the colon may or may not be marked. The local symptoms in some cases of epidemic dysentery are comparatively slight, and in general, so far as my observation goes, patients suffer far less in fatal cases than in sporadic cases wholly devoid of danger. Nausea and vomiting occur oftener in the epidemic than in the sporadic disease. In epidemic dysentery albumen and casts in the urine are occasionally observed.

The differences, as regards the general symptoms, in different epidemics and in different cases are marked. Severe cases are characterized by prostration, feebleness of the circulation, coldness of the surface—in short, by symptoms denoting adynamia. The pulse may become frequent, small, soft, and vibratory but compressible, or it may be small, weak, and thready, with but little, and sometimes not any, increase of frequency. These characters of the pulse, denoting feebleness of the action of the heart together with other adynamic symptoms, are developed in some cases early in the disease, without having been preceded by active febrile movement; but in other cases the pulse for a time is full and strong, the skin hot, the adynamia succeeding these symptoms of high fever. In fatal cases a condition analogous to the stage of collapse in epidemic cholera may precede, for a variable period, the termination of the disease. In this condition the pulse is scarcely appreciable or it is extinct; the surface is cold, and either dry or bathed in perspiration; the teeth are sometimes covered with sordes; the quantity of urine is greatly diminished; cramps of the muscles of the lower extremities sometimes occur; and this collapsed condition may exist for one, two, or three days before death. The mode of dying is by slow asthenia.

The intellect generally either remains intact or slight mental aberration occurs only in the latter part of life; but some cases are characterized by delirium. The patient talks incoherently under the influence of transient delusions; he may attempt to get out of bed, and requires to be restrained.

In a case which came under my observation the delirium was of a boisterous, mirthful character, the patient singing snatches of humorous songs, shouting, and attempting to get out of bed, after the pulse had become extinct and the surface of the body was cold like that of a cadaver. In this case the manifestations of delirium were so painfully incongruous that the patient was kept under the influence of chloroform for several hours before his death.

The delirium and other symptoms in some cases are analogous to those belonging to typhus and typhoid fever. The typhoid state may exist in cases of this disease as in various other affections. But it is to be borne in mind that dysentery sometimes occurs as a local complication of typhus and typhoid fever. Certain epidemics of these fevers are characterized by the occurrence of this complication. The distinction between dysentery with typhoid symptoms, or typhoid dysentery, and typhus or typhoid fever with a dysenteric affection developed secondarily, is the same as between typhoid pneumonitis and typhus or typhoid fever complicated with pneumonitis. The symptoms of scorbutus are associated with those of dysentery when, as is sometimes the case, the latter prevails among persons who are suffering from scorbutic deterioration of the blood. So in districts where periodical fevers prevail, epidemics of dysentery may be characterized by periodicity as regards febrile movement, etc., due to the union of dysentery with intermittent or remittent fever or the conjoined operation of the special cause producing the latter.

The duration of the disease in cases of epidemic dysentery is very variable. In malignant epidemics the disease sometimes runs very rapidly to a fatal issue, the collapsed condition occurring perhaps in the course of a few hours. On the other hand, cases may be protracted to the third and fourth week before either convalescence or death takes place. As already stated, epidemics differ widely as regards the severity of the disease. In some epidemics the majority of cases are mild and the rate of mortality is very small, while in other epidemics the proportion of deaths is very large. The latter are justly distinguished as malignant. There are few epidemics more to be dreaded than those of malignant dysentery. They occur much oftener in tropical than in temperate climates, but there is no part of the world exempt from their occasional occurrence. Epidemic dysentery is one of the scourges of camps in time of war, especially if to causes operating particularly on armies tropical influences be added. It prevailed to a very great extent in the late civil war in this country among the national and the insurgent forces, especially in the Southern States, and it was often associated with phenomena referable to malaria.¹

Epidemic dysentery is an infectious disease. The special CAUSE is the same in epidemic and in sporadic dysentery. Reasoning analogically, this special cause is a specific micro-organism. The various agencies which appear to give rise to the disease, such as exposure to atmospheric vicissitudes, fatigue and hardships incident to army life, insufficiency of diet, overcrowding, malaria, etc., probably act as co-operating causes, rendering the system more susceptible to the dysenteric poison and giving rise to other morbid phenomena than those which the special cause would alone produce. Epidemics would perhaps not often occur were it not for the operation of accessory causes; hence the rationale of their occurrence in camps, in prisons, and in situations where numbers are exposed to hygienic influences conducive to the development of any disease. With respect to the source of the special cause of dysentery or the conditions under which it is generated and diffused we have at present no positive knowledge. The contagiousness of epidemic dysentery has been a much-mooted question. Without entering into any dis-

¹ Vide Woodward, second medical volume of *Med. and Surg. History of the War of the Rebellion*, Washington, 1879.

cussion of this question I shall content myself with saying that the evidence of communicability rests mainly on the successive occurrence of a greater or less number of cases among members of one household, or in persons who from proximity of residence are brought into contact with each other; and the diffusion of the disease under these circumstances may perhaps be satisfactorily accounted for by the fact that the persons attacked are alike exposed to the special cause together with the same co-operating causes. It is, however, proper to state that some distinguished authors suppose that the intestinal excreta contain a virus by means of which the disease may be communicated. That the virus is a *contagium vivum* has not as yet been proved by the discovery of a special micro-organism and the production of the disease by inoculation. Whether the disease be communicable or not, there are instances which seem to afford evidence that the special cause may be transported by means of clothing, etc.

The opinions of different writers and practitioners concerning the TREATMENT of dysentery, especially as an epidemic, show great diversity, and there is abundant testimony of the success of measures quite opposite in character. The fact just stated shows either that the recoveries were due mainly to an intrinsic tendency of the disease, or that the disease is presented at different times and places under different pathological phases, and the measures of treatment require to be correspondingly varied. Both explanations are doubtless measurably applicable. Sporadic dysentery as a rule, and epidemic dysentery in a certain proportion of cases, tend intrinsically to recovery. Recovery under these circumstances takes place, whatever be the treatment, provided it be not destructive. On the other hand, in a certain proportion of cases of epidemic dysentery the disease must, of necessity, end fatally. The extent of mucous surface affected, the loss of fluids by hemorrhage and transudation, and the destructive lesions which take place preclude recovery under any treatment; but it is also true that the different features which the disease assumes in different epidemics, and the various morbid conditions with which it may be associated, must more or less influence therapeutical measures.

Purgatives, especially of the saline class, may be as appropriate in epidemic as in sporadic dysentery; but they should be given cautiously or omitted if sero-sanguinolent dejections occur or if the symptoms denote much tendency to adynamia. Theoretically, it would seem that the removal of the fecal contents of the intestine would be more safely effected by large injections (irrigation) than by saline purgatives. It is very desirable to arrest or moderate the dejections just named, for these doubtless conduce to the condition of collapse into which patients are liable to fall. For this purpose opium is to be given in as large doses as are required or as are well borne, in conjunction with astringent remedies, such as gallic acid, acetate of lead, the persulphate or pernitrate of iron, rhatany, etc. I believe the main reliance should be placed on opium in some form in these cases, other remedies being considered as auxiliary. The latter, therefore, are not to be employed as substitutes for opium except in cases in which, from a constitutional peculiarity, this remedy in any form produces such distressing effects as to contraindicate its use. It should not be decided that opium cannot be tolerated on the assertion of the patient, but only after a fair trial.

In this disease, as in some others, there is frequently a wonderful tolerance of opium—a tolerance not to be explained by the antagonizing influence of pain, since it is manifested in cases in which pain is not a prominent symptom. Christison, in stating this fact, adds that he has known from 24 to 30 grains of the gum of opium to be taken in the course of twenty-four hours. I have given 2 grains hourly in the case of a female affected with dysen-

tery characterized by abundant sero-sanguinolent dejections, for the space of a week, without at any time symptoms denoting narcotism. I have met with a case exemplifying a still greater tolerance of this remedy. In this case, the patient not being habituated to the use of opium before his illness, the quantity of the sulphate of morphia given hourly was gradually increased to one grain, making 24 grains in the twenty-four hours, and this quantity was given for several consecutive days without any narcotism. Opium is not to be given as a matter of course in doses approaching these, but it is to be given with a view to the desired end—namely, the arrest of the sero-sanguinolent dejections; and if this effect be not obtained the doses are to be increased to the amount which will be borne without narcotism, be the amount never so large. It is hardly necessary to say that in increasing the dose the condition of the patient is to be carefully watched; and attention is to be directed to the pupils and to the number of respirations, as well as to the soporific state, in order to avoid a cumulation which may result unexpectedly in narcotism. The quantity of opium which may with prudence and propriety be given in dysentery will vary greatly according to the varying tolerance in different cases.

In proportion as the symptoms denote a tendency to death by asthenia, the powers of life are to be supported by alcoholics and nourishment. The general principles which should govern the employment of supporting measures are the same as in other affections which in like manner tend to destroy life by exhaustion. Alcoholics are sometimes tolerated in large quantity in severe cases of this disease. I have known over 40 ounces of brandy to be taken in twenty-four hours by a patient who in health was not accustomed to the use of ardent spirits, and this large quantity produced no excitation of the circulation or nervous system. This patient was saved apparently by the persevering use of alcohol with large doses of the sulphate of morphia. I have repeatedly seen patients recover under the vigorous employment of supporting measures, conjoined with opium in large doses, when, as judged by the symptoms, the condition appeared to be truly desperate; yet of the cases properly distinguished as malignant many must die, despite the faithful employment of the measures on which the chief reliance is to be placed.

Dysentery associated with phenomena denoting the operation of the special cause of periodical fever calls for treatment having reference to the latter, in addition to the measures addressed to the dysenteric affection. Quinia is a highly important remedy in these cases. Associated with scorbutus, the dietetic and remedial measures appropriate to this condition are indicated. Occurring as a complication of the continued fevers, it furnishes an additional indication for the supporting measures which these fevers claim irrespective of the dysenteric complication. Coexisting rheumatism calls for the addition of the remedies appropriate for this disease.

Chronic Dysentery.

The anatomical basis of chronic dysentery is chronic inflammation of the large intestine, with or without ulceration. The term, however, is sometimes applied to cases of functional diarrhœa, and on the other hand the term chronic diarrhœa is often applied to cases of chronic dysentery. The distinction between chronic diarrhœa and chronic dysentery is usually based upon the character of the stools. It is impossible, however, to draw a sharp boundary-line between the two processes. Woodward even takes the ground that no distinction is admissible. He says:¹ "The results of any attempt to sub-

¹ Woodward, second medical vol. of the *Med. and Surg. History of the War of the Rebellion*, Washington, 1879, p. 483.

divide these cases into chronic diarrhœa and chronic dysentery in accordance with the presence or absence of tenesmus or of mucus, muco-pus, pus, or blood in the stools, or any other clinical evidence with which I am acquainted, would not be found to correspond with any anatomical classification." He therefore includes under the name chronic diarrhœa all the chronic alvine fluxes with the exception of those resulting from tuberculous ulceration of the intestine; but, as in many other processes which cannot be sharply separated from each other, it is here convenient to retain the old names, although the assignment of certain cases to one class or to the other may be more or less arbitrary. Typical cases of chronic diarrhœa, however, are sufficiently distinguishable from typical cases of chronic dysentery.

Chronic dysentery very rarely occurs in this climate, save as a sequel of acute dysentery. Recovery from the latter does not take place, but the inflammation becomes chronic, or more commonly ulcerations which take place during the acute affection do not cicatrize, but continue for an indefinite period. Acute exacerbations often occur in the course of chronic dysentery. Acute dysentery, however, very rarely eventuates in the chronic form of the disease in temperate climates, and hence chronic dysentery is rare in these climates. It is otherwise in warm climates. Here the chronic often follows the acute affection. Chronic dysentery in tropical climates may also begin insidiously without an acute attack. Chronic dysentery thus prevails chiefly in tropical countries or among those who have contracted dysentery in these countries. In the Northern States of the Union the cases observed are, for the most part, imported from the South. Of the soldiers who returned from the war in Mexico, large numbers were affected with this disease, and during the late civil war cases were abundant among the soldiers sent to the Northern military hospitals from different points in the Southern States.

The lesions observed in chronic dysentery are the result of inflammation of the mucous and submucous coats of the large intestine, with or without ulceration. Chronic inflammation without ulceration presents an appearance in many respects similar to that already described for acute simple inflammation of the large intestine. Instead of bright red, the color of the mucous membrane is more frequently bluish-red, or some hue due to the deposit of dark pigment, as brown, slate-color, or ash-color. The pigmentation may be both in the follicles and in the mucous membrane outside of the follicles. The mucous and submucous tissues are thickened, usually more in some places than in others. The wall of the intestine often feels stiff and hard. Its calibre may be diminished. The mucous membrane may present many small elevations lying close to each other and producing the so-called mammillated appearance. In rare cases large polyp-like excrescences, consisting of hyperplastic connective tissue containing glands and covered with columnar epithelium, are produced, and may be present in large number (enteritis polyposa). Sometimes little projecting cysts, varying in size from a pin's head to a pea and containing clear mucus, are observed beneath the mucous membrane. These are formed by the dilatation and coalescence of the tubules of Lieberkühn. They generally occupy the site of the solitary follicles. As pointed out by Cornil, and especially by Kelsch,¹ the solitary follicles in dysentery, particularly in cases with follicular enlargement and ulceration, are not infrequently invaded by distension and new growth of the adjoining tubules of Lieberkühn. The thickening of the mucous and submucous coats in chronic dysentery is due partly to infiltration with new cells and partly to new formation of connective tissue. There is, however, less tendency toward the development of new fibrillated connective tissue in chronic dysentery than in the chronic inflammation of most mucous membranes. Hence, complete

¹ *Archives de Phys. norm. et path.*, 1873, pp. 406 and 573.

recovery is possible after long duration of the disease. In some cases of chronic dysentery enlargement and ulceration of the solitary follicles are very prominent, and constitute almost the sole lesions. Such cases are called follicular inflammation or follicular dysentery. In many of these cases the growth of the glands of Lieberkühn into the follicles has been observed by Kelsch and by Woodward. Swelling and ulceration of the follicles, however, frequently occur without any such growth.¹

The ulcers which may occur in dysentery are of three kinds: first, follicular; second, non-follicular or simple (catarrhal); and third, diphtheritic. These varieties are often combined. The follicular ulcerations are the result of softening and breaking down of the swollen solitary follicles, either in their centres or at their apices. The ulcer at first presents a little, round, constricted opening, as if punched out, leading into an irregular cavity in the mucous or submucous tissue. It extends peripherally more rapidly in the submucous than in the mucous coat, and hence often presents overhanging edges, even when of considerable size. By extension and coalescence of these follicular ulcers large losses of substance in the inner coats of the intestine are produced. Ulcers unconnected with the follicles are formed by dense infiltration of the mucous membrane with pus-cells. By softening and molecular disintegration of the intercellular substance, first in the upper layers, superficial ulcers are produced. These extend in depth and in superficies by continuance of the purulent infiltration and by liquefaction of the basement-substance. These ulcers possess no very distinctive characters. They resemble closely those produced by diphtheritic sloughing. The method of formation of diphtheritic ulcers has already been sufficiently described under the head of Acute Dysentery. When the fibrinous exudation and the sloughing process disappear, these ulcers extend by the same process of suppuration as the preceding. They usually present abrupt or sloping edges, but may have undermined walls. In fact, when dysenteric ulcers attain to a large size, it is generally impossible to tell in what way they have originated. Any of these ulcers may extend in depth so far as to perforate the intestinal wall, but this is a rare occurrence. Recovery from dysentery with ulceration is effected by cicatrization of the ulcers. Some ulcers may cicatrize while others are extending. There is nothing characteristic regarding these cicatrices except in the case of those resulting from small follicular ulcers. The cicatrices of these small follicular ulcers are stellate in shape. The radiating ridges extend into the substance of the surrounding mucous membrane, and enclose between them mucous membrane somewhat modified, but containing the glands of Lieberkühn (Woodward). Allusion has already been made to the occasional occurrence of stricture of the intestine from contraction of the cicatrices resulting from dysenteric ulcers. Waxy degeneration of the intestinal mucous membrane has been occasionally observed in cases of dysentery. Acute diphtheritic inflammation may occur at any time during the course of chronic dysentery, and may lead to a fatal issue. Of the diseases which may complicate chronic dysentery, peritonitis, hepatic abscess,

¹ Kelsch (*loc. cit.*) describes a form of dysentery prevalent in tropical countries in which embryonic or granulation-tissue develops in the mucous membrane and obliterates most of the glands of Lieberkühn. Portions of these glands undergo cystic distension and invade the solitary follicles. Embryonic cells collect in especially large number about Brücke's muscle and infiltrate also the submucosa. The disease begins insidiously, and, unless acute attacks occur, no ulceration takes place. If there be an acute attack, the accumulation of pus-cells about the vascular plexus beneath the mucous membrane becomes so great as to shut off the nutritive supply to the tissue above, and gives rise to sloughing of the mucous membrane. Kelsch denies that a fibrinous or diphtheritic exudation ever occurs in dysentery; but his observations are based upon an insufficient number of cases.

and pneumonitis should be mentioned especially. Abscess of the liver is a frequent complication in tropical, but is rare in temperate, climates. It is generally in the form of small multiple abscesses.

In chronic dysentery the evacuations vary in character. They contain at times thin or pultaceous feces, and occasionally scybala. Their most characteristic ingredients are mucus, pus, and blood; mucus, however, may be absent. Flakes of pseudo-membrane and of necrosed tissue are present only when an acute diphtheritic inflammation supervenes. Undigested particles of food are often present, especially when substances difficult of digestion are taken. Woodward applies the term *yeasty* to frothy stools containing bubbles of carbonic acid and the yeast-fungus. These may be observed when the digestion is greatly impaired and amylaceous articles of food are taken. The stools are usually accompanied with griping pains. Tenesmus is less frequent than in acute dysentery. In some cases the evacuations are unattended with any feeling of distress. The stools vary from three or four to twenty or more in the twenty-four hours. There may be intervals in which constipation takes the place of the frequent discharges. The accumulation of gas in the intestines and the escape of flatus may be annoying symptoms. In severe cases the stools are always loose and thin and contain mucus, pus, and blood. In these cases it is to be inferred that the inflammation extends over the whole or the greater part of the large intestine. In other cases dysenteric discharges occur more or less frequently in alternation with fecal dejections. In these cases the inflammation is less diffused. If the evacuations be generally or frequently solid or moulded, the dysenteric evacuations being superadded, the inflammation or lesions are circumscribed and situated near the anus. In these cases ulcerations may sometimes be seen if examination be made with the speculum. There is generally more or less tenderness along the line of the colon.

Chronic dysentery is one of the most intractable and hopeless of diseases. For a time, if the evacuations be held in check by palliative measures, the appetite and digestion not being greatly impaired, the general aspect and strength may not show much deterioration, but at length the appetite and digestion fail, and the continued irritation and loss of fluids induce progressive emaciation and debility. The duration of the disease extends usually over several months, and sometimes years. If not destroyed by some intercurrent affection, the patient becomes extremely emaciated and is reduced almost to a skeleton; the surface is usually dry, cool, or cold; the pulse becomes more and more feeble; the mental faculties are weakened, delirium rarely occurring, but the mind in certain cases falls into an apathetic state, the patient being indifferent to, and taking but little notice of, persons and things around him. Anorexia becomes complete, and vomiting in some cases is a prominent symptom; œdema of the lower limbs sometimes occurs; ulceration of the cornea is an occasional event, and I have known the cornea to be perforated, with loss of the humors of both eyes. The mode in which a fatal termination takes place is generally typical of dying by slow asthenia. The immediate cause of death is sometimes general peritonitis from perforation of the intestine. Parenchymatous nephritis is not an infrequent complication, but uræmic coma and convulsions are rare. Woodward states that "sudden death was a not infrequent occurrence, and attracted considerable attention during the war."¹

The DIAGNOSIS of chronic dysentery is not always easy. The disease is to be discriminated from functional diarrhœa, and this is not always readily done. The presence of pus, mucus, and of blood at times, if not frequently or constantly, is the important point in the differential diagnosis. It is also

¹ *Op. cit.*

to be discriminated from ulceration of the large intestine due to tuberculosis, carcinoma, or other cause. Tuberculosis may be excluded if the lungs be free from the deposit of tubercle. In carcinomatous disease frequently a tumor is to be felt through the abdominal walls, or if seated in the rectum it is accessible to examination by means of the touch and speculum. The fact that in the great majority of cases chronic is preceded by acute dysentery is highly important in the diagnosis. We may conclude at once that the disease is chronic dysentery if it have followed the acute disease; and the latter fact may generally be ascertained without difficulty, owing to the well-marked diagnostic symptoms of acute dysentery. In temperate climates the affections with which chronic dysentery is liable to be confounded are most likely to exist in cases of doubt, owing to the infrequency of the latter.

The TREATMENT of chronic dysentery relates *first* to the local affection. Remedies to allay irritation and to promote the healing of ulcerations are indicated; but, unhappily, in the great majority of cases there is very little probability that a cure will be effected, and all that can be hoped for from judicious treatment are palliation of symptoms and prolongation of life.

Certain remedies have been employed with a view to their direct action upon the affected portions of the intestines. The nitrate of silver is one of these; but it is absurd to suppose that this remedy, given as largely as prudence will allow, passes through the stomach and small intestines unchanged. Whatever benefit may be derived from it, therefore, is not to be explained on the ground of its topical application to the diseased surface. The balsamic medicines—particularly the balsam of copaiba—have been given for the same purpose, and with more reason; but clinical observation shows not much benefit to be derived from them. The subnitrate or the subcarbonate of bismuth may be included among the remedies supposed to act by coming in contact with the affected parts. This remedy is often beneficial as a palliative, the dejections becoming less frequent, with relief of pain, etc., under its use. It should be given in doses of from 20 to 30 grains three or four times daily. Some have recommended much larger doses, and, given almost without limit, it produces no deleterious effects; but probably all the benefit to be derived from it is secured by the doses just indicated. Its administration in enemas has been advocated in this disease. The various astringent remedies are to be tried in succession. Of those most likely to be useful the following may be mentioned: tannic or gallic acid, alumen, rhatany, *rubus villosus* (blackberry-root), and the persulphate or pernitrate of iron. The oxide of zinc is considered by many as a useful remedy.

In so far as the dejections are controllable by the foregoing remedies, they should be relied upon to the exclusion of opium, because they will interfere less with appetite and digestion. Opiates, however, will be required to a greater or less extent in conjunction with other remedies. So far as practicable, they should be administered by the rectum, either in enemas (a salt of morphia or some liquid preparation contained in an ounce of mucilage or thin starch-water) or in suppositories. The lower part of the rectum should be examined with the speculum, and appropriate topical applications made if ulcers in this situation be discovered. Dr. Maury and Prof. T. G. Thomas have reported cases in which remarkable benefit followed the application of nitric acid to ulcerations within the rectum; and they call attention to the fact that by means of a speculum the interior of the bowel may be brought into view as far as the sigmoid flexure.¹ The removal of fecal collections and of other irritating material, by means of large injections given through a flexible tube introduced into the sigmoid flexure, deserves trial in chronic as-

¹ Vide *New York Med. Journ.*, Jan., 1876, and the author's *Clinical Medicine*, p. 292 *et seq.*

in acute dysentery. Prudence, however, dictates caution in the introduction of the tube and as regards the quantity of water introduced, lest rupture at an ulcerated spot may be produced.

The treatment relates, *secondly*, to the system. In relative importance the general take precedence of the local measures. The surface of the body should be well protected against atmospheric changes. The diet should be nutritious but bland, articles of food being selected which do not leave much indigestible matter to pass into the large intestine. Milk, eggs, and farinaceous food are generally best suited, but in some cases animal food is found to agree. The plan of diet is to be governed by experimental trials. Tonic remedies and alcoholic stimulants are indicated by defective appetite and digestion. Of tonic remedies, quinia, the chalybeate preparations, the mineral acids, and the bitter infusions are to be employed in succession. The use of alcoholic stimulants is to be regulated by their effects in individual cases. Moderate out-of-door exercise and mental recreation are important. Change of climate is sometimes effectual when other measures prove unavailing. The experience of the late war showed the happiest effect of transferring soldiers from the South to Northern hospitals in salubrious rural situations.

Inflammation and Perforation of the Cæcum—Fecal Abscess.

Inflammation of the cæcum, the inflammation limited to this portion of the large intestine, constitutes an affection called *typhlitis*, *typhlo-enteritis*, or *cæcitis*. Acute inflammation confined to the cæcum is not of frequent occurrence. The symptoms are—pain and tenderness within a circumscribed space corresponding to the situation of the cæcum, with vomiting, sometimes constipation and sometimes diarrhoea, and febrile movement. It is liable to be confounded with phlegmonous inflammation connected with disease of the vertebrae, renal calculus, circumscribed peritonitis from perforation of the vermiform appendix, and inflammation of the right ovary. Peritoneal inflammation, limited to the portion of peritoneum covering the cæcum, may accompany the affection. The pain and tenderness are then more marked, and the cæcum is distended by an accumulation of gas, the peritoneal inflammation producing paralysis of the muscular tunic. The distension sometimes is so great that a circumscribed prominence corresponding to the area occupied by this portion of the large intestine is manifest to the eye and may be felt through the abdominal walls. Extension of the limbs may occasion pain, as in cases of general peritonitis. The cases which I have seen have terminated in recovery. I have not met with perforation followed by either general peritonitis or fecal abscess in a case of acute inflammation of the cæcum. The probable explanation is that in these acute cases circumscribed peritonitis gives rise to an agglutination of peritoneal surfaces, which is protective against perforation. Subacute inflammation gives rise to symptoms less distinctive. It may occur, and recovery take place, without the development of symptoms denoting an affection of importance; but it becomes a very important affection when it leads to ulceration and perforation of the intestinal coats.

If the perforation take place in that portion of the cæcum not invested with the peritoneum, the gaseous and other contents of the intestine, escaping into the areolar tissue, give rise to inflammation which may be either diffused or circumscribed, in the latter case forming an abscess called a fecal abscess. If diffused, the inflammation may extend more or less over the abdominal walls, which become swelled, pitting on pressure as in œdema, with a feeling of crepitation due to the permeation of intestinal gas. If an incision be made,

a dark, sanious liquid escapes with gas emitting an intestinal odor. Under these circumstances a fatal result is inevitable. If, however, the perforation lead to a circumscribed abscess which opens externally, gas and fecal matter, with pus, escape; a fistulous communication with the intestine is established; and this may remain permanently, or it may gradually close and recovery take place.

Perforation at a point where the intestine is covered with the peritoneum may give rise to diffuse peritonitis, which in most cases, if not invariably, is fatal. Often, however, the escape of the intestinal contents into the peritoneal cavity is prevented by a prior circumscribed peritonitis resulting in protective adhesion of the peritoneal surfaces. Under these circumstances a perityphlitic abscess follows, and this is liable to rupture into the peritoneal cavity if timely surgical interference be not resorted to.

The causes of inflammation of the cæcum, whether it be acute or subacute, are probably the detention in this situation of the feces, and the presence of irritating matters either received with the ingesta or arising from chemical changes within the intestine. Over-exercise and exposure to cold may be auxiliary causes.

Complete rest is an essential part of the treatment. This should be rigidly enforced when the inflammation is subacute not less than when it is acute. The importance of this part of the treatment relates to the prevention of perforation. It is desirable to effect the removal of the contents of the cæcum, but active purgatives are fraught with danger. Mild laxatives only are admissible, such as castor oil or small doses of Epsom salts. It is perhaps safest to rely upon enemata given through a long flexible tube carried upward to the sigmoid flexure. These may be repeated at short intervals; that is, three or four times daily. A warm poultice or the water-dressing should be applied over the site of the cæcum. Blisters and other counter-irritant applications are of doubtful utility. The ingesta should be restricted to animal broths and milk with the addition of lime-water. Opiates should be given in doses sufficient to relieve pain. After the disappearance of the symptoms denoting inflammation, the diet for some time should be regulated with reference to a small quantity of fecal residue. Constipation should be avoided by means of mild laxatives, and physical exercise should be interdicted.

Perforation of the cæcum from an ulcerative process may take place without having been preceded by local symptoms denoting any important affection. It occurs perhaps when patients are engaged in their usual avocations. A localized sharp pain is usually felt at the time of the perforation, followed by circumscribed tenderness. These symptoms should at once excite suspicion. Within the area of the pain and tenderness, situated in the right iliac fossa, a sense of resistance is shortly felt by the touch, the boundaries of which may not be sharply defined. On percussion there may be either flatness or a tympanitic resonance, the latter, if limited to the area of tenderness, being due to gas escaping through the perforation. In the course of a few days fluctuation is appreciable.

As regards DIAGNOSIS, fecal or perityphlitic abscesses are to be discriminated from psoas abscess in Pott's disease, abscess with caries of pelvic bones, cellulitis, abscess originating in the abdominal wall, perinephritic abscess, and disease of the hip-joint. Tympanitic resonance on percussion and crepitation from the presence of intestinal gas are diagnostic points.¹ The tympanitic resonance, if ascertained not to be transmitted from the cæcum, distinguishes this abscess from phlegmonous suppuration, which is primarily extra-cæcal;

¹ Vide an analysis of 32 cases, by Prof. Roberts Bartholow, in the *Amer. Journ. of Med. Sciences*, Oct., 1866.

that is, not secondary to perforation. An abscess, however, originating in either the connective tissue behind the cæcum or in the abdominal wall may lead to perforation of the intestine. In the latter case, if the abscess do not discharge its contents into the intestine and a fluctuating tumor remain, the differential diagnosis is not important practically, since the treatment indicated is the same as if the perforation preceded the abscess.

An abscess connected with perforation of the cæcum if treated only by rest, fomentations, and anodyne remedies may open externally, as already stated, and recovery follow. The recovery may be rapid, as in an instance which I have reported.¹ The discharge may take place into the intestine, and recovery may follow closure of the perforation. An opening may take place into the bladder and fecal matter be passed with the urine. I have met with an instance of this kind. There is, however, danger of the discharge of pus into the peritoneal cavity, and consequent fatal peritonitis. The pus is rarely absorbed. It may migrate in different directions for a considerable distance. In a case which I saw with Dr. Damainville of New York, it made its way above the diaphragm into the bronchial tubes, and was discharged by expectoration. The case ended in recovery.

The TREATMENT which has proved successful in the hands of many surgeons in this country is that inaugurated by Prof. Willard Parker in 1867. It consists in removing the pus, either by aspiration or by a free opening, as soon as fluctuation is felt and the presence of pus demonstrated by an exploratory puncture. This method is a highly important improvement in the treatment of perityphlitic or fecal abscess. (Further details belong to surgery.²)

Absolute rest is to be enjoined until recovery; cathartics are to be avoided, and the patient should be restricted to a purely nutritious diet.

Inflammation and Perforation of the Vermiform Appendix—Appendicitis.

The appendix is, in fact, a part of the cæcum, but inflammation and perforation here may occur independently of any affection of the cæcum proper. The term typhlitis is applied to inflammation of the vermiform appendix as well as to cæcitis. Perforation of the cæcum is much more infrequent than of the appendix.

Inflammation of the appendix is caused either by the entrance of irritating substances within its cavity or by distension from fecal matter. The communication of its cavity with that of the cæcum may become closed, and dilatation may result from the accumulation of inflammatory products. It may be dilated so as to form a tumor of considerable size. My colleague, Prof. Janeway, has seen a case in which it formed a tumor as large as a child's head, and another case in which it was as large as a Bologna sausage.³ Whenever moderately enlarged it may be felt as a tumor through the abdominal walls. The tumor in cases reported by James Jackson, in his *Letters to a Young Physician*, under the title "A Painful Tumor near the Cæcum," was doubtless an enlarged appendix. I have met with a case in which five previous attacks had occurred. In this case the tumor and all the symptoms disappeared after the discharge of pus from the bowels. At the meeting of the International Medical Congress in Copenhagen in 1884 the late Dr. Mahomed related a case in which, after repeated attacks, an abdominal incision was

¹ Vide *Clinical Medicine*.

² For a table of 60 cases, with operations and results, collected by Dr. William C. Wey, vide *Trans. of Med. Soc. of the State of New York*, 1880.

³ *N. Y. Med. Record*, April 12, 1884.

made and a calculus removed from the appendix, the patient recovering and no subsequent attacks taking place.

Perityphlitis and fecal abscess may arise from inflammation and perforation of the appendix. Indeed, these affections are more likely to be connected with inflammation and perforation of the appendix to the cæcum than with diseases of the latter. The treatment is that already considered in connection with inflammation and perforation of the cæcum.

An important question is, whether in cases of intestinal perforation laparotomy be not admissible with a view to closure of the opening into the intestine and the removal of the irritating matter within the peritoneal cavity. In the light of the knowledge recently acquired respecting abdominal sections this operation appears not only warrantable, but advisable as a possible life-saving procedure under circumstances which without it render the prognosis almost of necessity fatal.

Perforation of the appendix, followed by diffuse peritonitis, is often not preceded by symptoms denoting acute inflammation. In cases which have come under my observation the patients generally had had uncomfortable sensations in the iliac region for two or three days, and in many instances had taken some cathartic medicine, thinking that they were "bilious" or needed "clearing out." Suddenly a sharp, lancinating pain was followed by the symptoms of diffuse peritonitis, which proved fatal. At the autopsy, generally within the appendix hard bodies are found to which it is customary to attribute the perforation. These bodies are usually of small size (from a pea to a date-stone), and consist of hard feces, a calcareous material, the seeds or stones of fruit, etc. If nothing be found, the supposition is that the bodies have escaped through the perforation.

Perforation of intestine in cases of diffuse peritonitis is referable, as a rule, to the appendix, if not preceded by notable intestinal or gastric symptoms. The evidence for and against the occurrence of perforation as the cause of diffuse peritonitis will be considered in connection with the latter affection.

In the exceptional instances of recovery when diffuse peritonitis has been thus induced the appendix quickly becomes adherent to adjacent parts, and the perforation is in this way closed. I have met with fatal cases in which the appearances after death showed more or less progress toward this result. In the examination of bodies dead with other diseases old adhesions are not infrequently found. They are probably results of circumscribed peritonitis secondary to disease of the appendix. Adhesion, taking place before perforation occurs, protects against diffuse peritonitis; but fecal abscess may follow, as in cases of perforation of the cæcum. I have seen a specimen in which the appendix was attached to the bladder and perforation had taken place, causing a vesico-intestinal fistula. The first evidence of this was the appearance of a lumbricoid worm at the end of the penis, the patient then being eight years of age. Subsequently, other worms were discharged with the urine, and repeatedly the seeds of fruit. Most of the urine was discharged by the bowels. The fistula for many years gave but little inconvenience. The patient served as a soldier in the late civil war. He was operated upon for stone in the bladder, and died five days after the operation, the fistulous communication of the bladder with the appendix having existed for twenty years.

[McBurney lays great stress upon the diagnostic importance of determining the *seat of greatest pain on pressure*. In every case under his observation "the seat of greatest pain *determined by the pressure of one finger* has been very exactly between an inch and a half and two inches from the anterior spinous process of the ileum, on a straight line drawn from that process to the umbilicus. This may appear to be an affectation of accuracy, but so

far as my experience goes the observation is correct."¹ "McBurney's tender point" is now ranked among the diagnostic signs of appendicitis.—H.]

Pain or uneasiness referred to the right iliac fossa, without other symptoms of disease, should always excite apprehension in the mind of the physician. Rest should be enjoined and cathartics avoided. By these precautions, if patients seek advice prior to perforation, its occurrence may perhaps be prevented.

[The TREATMENT of appendicitis depends to some extent upon whether the attack is the first from which the patient has suffered. If it is, he should be compelled to keep in bed with an ice-bladder applied over the seat of pain and tenderness, while the diet is limited to milk and animal broths. In case of constipation the bowels should be moved with small (fractional-grain) doses of calomel. The greatest difference of opinion exists concerning the use of opium in this disease. Surgeons, for the most part, are decidedly averse to its employment, while many physicians are accustomed to prescribe it in full doses. The truth doubtless lies between these extremes. The tranquillity of mind, the relief from pain, and the sleep obtained by the judicious use of opiates exert a favorable influence upon the course of the disease. On the other hand, some surgeons contend that the relief obtained by opium and its alkaloid morphia induce a false sense of security and lead to the postponement of surgical measures to a period when they are employed under disadvantageous circumstances. Opium, however, need never be given in doses sufficient to produce a state of narcosis, and even if pain and tenderness are completely abolished by it, it must be borne in mind that these are not the only symptoms of appendicitis. The febrile movement and the physical signs of the local affection, such as tumor, induration, and dulness on percussion, continue in spite of the use of opium, and afford the most reliable indications concerning the progress of the case. The prejudice against opium on the part of surgeons is doubtless partly attributable to the fact that they are generally called in by physicians to decide upon the question of operation, and frequently are called too late. They see the cases in which medical treatment has failed, and are apt to conclude that medical treatment is always useless. They do not see the numerous cases in which a cure has been obtained by strictly medicinal means. It must be acknowledged, however, that the majority of cases—probably two-thirds—sooner or later demand surgical treatment, and it is desirable, therefore, to be acquainted with certain general rules by which such cases may be recognized. The following have been formulated by Prof. Fitz of Harvard:

Surgical treatment is indicated for "urgent symptoms (rising pulse and temperature, increasing distention, and spreading pain) with or without a tumor, and for a tumor with or without urgent symptoms. Recurrent attacks should be treated as first attacks. If recurrence is so frequent as to debar the patient from the enjoyment of life or the ability to earn a living, removal of the appendix between the attacks should be advocated."—H.]

Colitis—Proctitis.

Inflammation of the colon (colitis) and of the rectum (proctitis) furnishes the anatomical characters of dysentery. But in the latter the inflammation involves a special cause; hence dysentery is with propriety included among the infectious diseases, using the term infectious in the sense now generally adopted. The terms colitis and proctitis may be applied to inflammation in the colon and in the rectum when it occurs irrespective of a special causa-

¹ *New York Medical Journal*, Dec. 21, 1889.

tion. These terms will then correspond to the ordinary catarrhal inflammation of many authors.

Colitis, in this scope of the term, is rarely acute, but as a subacute affection it is not rare in the adult, and is common in infancy. It enters into the disease known as cholera infantum or the ileo-colitis of childhood. It may or may not be associated with inflammation seated in the small intestine (enteritis). In the cases among soldiers grouped by Woodward under the name of Acute Diarrhœa, inflammation affected especially the large intestine. The local symptoms are colicky pains, diarrhœa, the dejections being loose or watery and containing gelatinous mucus in greater or less quantity, with absence of tenesmus. Tenderness may be present, either limited to or most marked in the situation of the colon. The diagnosis is to be based on these symptoms. Fever, anorexia, and general debility are associated with these symptoms, and are proportionate to the degree and extent of inflammation.

The causes are the accumulation of feces, and especially the presence of undigested irritating matters received from the small intestine. General causes, such as over-fatigue, exposure to cold, insufficient alimentation, intemperance, etc., co-operate with the local causes, increasing the susceptibility to the latter and impairing tolerance. Hence the greater frequency and the greater severity of the disease in military campaigns than in civil life.

The general principles of the treatment are essentially the same as in cases of sporadic dysentery.

There is no practical advantage in endeavoring to distinguish chronic colitis from chronic dysentery, although the distinction may be admissible on anatomical and pathological grounds.

Proctitis occurs from the action of local causes, and it may simulate dysentery as regards the presence of mucus and blood in the dejections, together with tenesmus. Diarrhœa is wanting, and the clinical history in other respects lacks the features of a truly dysenteric disease. Perforation of the rectum sometimes gives rise to periproctitis and fecal abscess. These purely local affections of the rectum are properly surgical.

Reference may be made here to the occasional expulsion, *per rectum*, of membraniform casts of the intestinal tube. These have been observed a foot and more in length. They have been supposed to be the mucous membrane itself exfoliated, but oftener they have been mistaken for fibrinous exudation. They consist of inspissated mucus, and usually do not contain fibrin or coagulable lymph. In a case which came under my observation a number of casts were expelled, one of which was fifteen inches in length, one and a half inches in breadth, and from one-fourth to one-eighth of an inch in thickness. This specimen, examined by Professor Wm. H. Welch, was found to contain fibrillated fibrin, a large number of pus-cells, mucous corpuscles, with bacteria, red blood-corpuscles, and a few cylindrical epithelial cells. Their expulsion is preceded and accompanied by colicky pains and diarrhœa, the dejections containing blood and muco-pus. In most instances the casts are expelled repeatedly after variable intervals. The patients are generally women who manifest hysterical phenomena, and uterine troubles are often associated.

The casts are probably formed in the large intestine, and in connection with other symptoms they denote inflammation. The affection is therefore a variety of colitis. It has received a variety of names. DaCosta, who has reported a number of cases,¹ calls it *membranous enteritis*. The name *tubular diarrhœa* was proposed by John Mason Good, and to this name Woodward gives the preference, as implying no theory. (The reader is referred to the

¹ *American Journal of the Medical Sciences*, Oct., 1871.

Medical History of the War of the Rebellion, p. 363, for a full reference to the literature of this curious intestinal affection.)

Acute Enteritis.

The term *enteritis* signifies, literally, intestinal inflammation. Various significations have been attached to it by different writers. The older writers described under this name inflammation of the serous coat of the intestine, but modern authors, almost without exception, apply the term to inflammation of only the mucous and submucous layers. Many pathologists understand by enteritis inflammation of any part of the intestinal tract, and consider as subdivisions of enteritis duodenitis, jejunitis, ileitis, typhlitis, colitis, and proctitis. There are clinical grounds for distinguishing as separate affections duodenitis (usually in conjunction with gastritis), typhlitis, and proctitis, but it is impossible to distinguish, clinically, jejunitis and ileitis. It has already been remarked that diffuse inflammation of the large intestine is liable to involve the lower part of the ileum; and it is likewise true that inflammation of the small intestine frequently extends into the large intestine. As we already have in the words dysentery and colitis names for inflammation of the large intestine, it has become a conventional usage in this country, and to an extent elsewhere, to apply the term enteritis particularly to inflammation of the small intestine. The fact, however, is recognized that as in dysentery the inflammation often involves the ileum, so in enteritis, with even greater frequency, the inflammation extends to the upper part of the large intestine. It will be found that in most of the cases here described as enteritis the inflammation is most intense in the ileum, the cæcum, and the upper parts of the colon. The inflammation may be, however, nearly or quite confined to the small intestine.

ANATOMICAL CHARACTERS.—As the disease in itself rarely proves fatal, the opportunity of inspecting the appearances after death is not often offered. The changes are essentially the same as those described for acute simple inflammation of the large intestine (p. 398). The mucous membrane presents an arborescent redness, either diffuse or in patches. Ecchymoses within and beneath this membrane may be observed. Its surface is coated with mucus and muco-pus. An increased transudation of serum occurs, which, combined with rapid peristole, causes fluid stools. The mucous and submucous tissues are swollen in consequence of œdema, congestion, and cell-infiltration. The enlargement of the villi gives a plush-like appearance to the surface of the mucous membrane. The solitary and agminated follicles usually are swollen and appear as grayish-white elevations surrounded by a red, congested zone. Microscopical examination shows a variable number of emigrated white blood-corpuscles in the submucous and mucous coats. The same remarks are applicable to the desquamation of the epithelium here as in acute simple inflammation of the large intestine.

CLINICAL HISTORY.—The local symptoms in cases of acute enteritis are pain, tenderness on pressure over the abdomen, especially over the lower part of the ileum and the cæcum, and frequently diarrhœa, with nausea and vomiting. The pain is not intense, and is of a dull, aching character, with exacerbations, in which it resembles the pain of colic. The pain is referred to the umbilical region. The tenderness is not great. Slight pressure is well borne, but deep, firm pressure occasions more or less suffering. Diarrhœa is often, but not always, present. If present, the dejections are more or less frequent, loose, watery, and gelatinous. Tenesmus and the characteristic dejections of

dysentery are wanting. I have met with fatal cases in which diarrhoea has not occurred, the inflammation having been limited to the small intestine, as shown by the autopsy. If diarrhoea be a prominent symptom, it probably denotes an extension of the inflammation into the cæcum and colon. Vomiting is generally more or less prominent as a symptom. It may be excited sympathetically, or it may denote an extension of the inflammation to the duodenum and stomach. If jaundice occur it denotes duodenitis. The general symptoms vary considerably in different cases, the variations probably corresponding to the extent as well as the degree of the inflammation. The febrile temperature is in most cases moderate or slight, and the prostration is not great. The intellect is unaffected, except in severe cases, when delirium may occur, together with tympanites, hiccough, and symptoms denoting adynamia. The duration in favorable cases is brief, convalescence being declared in from a week to ten days.

PATHOLOGICAL CHARACTER.—Excluding enteritis occurring in connection with typhoid fever, tuberculosis, and the diseases of infancy, the disease has no special pathological character. It is a simple inflammation of a mucous membrane (intestinal catarrh). It occurs only as a sporadic disease, in this respect differing from dysentery. It differs also from dysentery in not leading to destructive lesions of the affected membrane, like those which occur especially in the epidemic form of that disease.

CAUSATION.—The susceptibility of the mucous membrane of the small intestine to acute inflammation after infancy is slight. It may be produced by dietetic excesses, the use of stimulating food and alcoholic drinks, poisoning with acrid substances, and the use of drastic purgatives. It is sometimes attributable to the action of cold upon the body when heated and perspiring, local causes being conjoined therewith. Fatigue and debility may co-operate with these causes.

DIAGNOSIS.—Acute enteritis is to be discriminated from dysentery, gastritis, colic, peritonitis, and typhoid fever. Assuming that the local symptoms are sufficient to denote inflammation somewhere within the abdomen, the absence of the characteristic dysenteric evacuations, of tenesmus, and of tenderness in the tract of the colon suffices to exclude dysentery. The microscopical examination of the stools may aid in determining the seat of the inflammation, as has been shown by Nothnagel. Under normal conditions Gmelin's reaction for bile-pigment with nitroso-nitric acid cannot be obtained in the feces or in the contents of the large intestine. If yellowish balls and clumps of mucus, or yellowish cylindrical epithelial cells which respond to Gmelin's test, be found in the feces, it is evidence of increased peristole, and often of inflammation in the small intestine. The presence of much undigested food, such as abundant starch-granules, in the feces is also evidence of increased peristole in the small intestine.

Nausea and vomiting, if unusually prominent, may suggest acute gastritis. But the symptoms of acute gastritis point distinctly to the stomach as the seat of disease. This disease may generally be excluded without difficulty. The two diseases, however, may be combined. The inflammation in some cases perhaps extends from the small intestine to the stomach; and in cases of poisoning with acrid substances the local effects of the latter may be produced within the small intestine as well as in the stomach.

Colic is a functional affection characterized by intense paroxysmal pain, without tenderness or febrile movement, and is oftener accompanied by constipation than by diarrhoea. These points are sufficient for its exclusion.

As regards the local symptoms, acute enteritis approximates to acute peritonitis more closely than to any other affection; but as a rule there is a marked disparity in the intensity of the symptoms in these two affections. The pain, tenderness, and tympanites common to both are, in the great majority of cases, notably greater in peritonitis. Diarrhoea, which is the rule in enteritis, occurs exceptionally in peritonitis. Rigidity of the abdominal muscles, which is one of the diagnostic symptoms of peritonitis, is wanting in enteritis. Moreover, the constitutional disturbance, as denoted by frequency of the pulse, prostration, etc., is much greater in peritonitis. Attention to these points renders the differential diagnosis easy in most cases.

The abdominal symptoms in typhoid fever may lead the physician to suppose that disease to be simply enteritis, and on the other hand a primary enteritis may be supposed to be typhoid fever. Typhoid fever is to be excluded by the absence of the diagnostic symptoms which attend its development and progress—namely, the characteristic rise of temperature, together with cephalalgia, epistaxis, bronchitis, the rose eruption, and delirium. Moreover, the adynamic symptoms in typhoid fever are generally greater than in simple acute enteritis, while the enteric symptoms are less marked.

PROGNOSIS.—Acute enteritis after infancy in the majority of cases is not a disease of great gravity. If it be not associated with any other important affection, and the patient have not a feeble constitution, a favorable prognosis may generally be entertained. The disease, however, sometimes ends fatally. This is to be apprehended when the pulse becomes feeble and frequent, the prostration marked, and delirium is developed, the local symptoms persisting. The mode of dying is by asthenia, as in cases of dysentery.

TREATMENT.—The indications for treatment may be embraced in a few words. An efficient but non-irritating purgative is generally at first advisable. Afterward opium in some form is to be given sufficiently to relieve pain and diarrhoea. It may be administered by either the mouth or rectum, or alternately in both modes, or by hypodermic injection. It is to be given in doses proportionate to the urgency of the symptoms, and graduated according to its effects. Fomentations over the abdomen by means of poultices, the water-dressing, or spongio-piline are useful. Moderate stimulation of the surface of the abdomen by sinapisms or liniments is appropriate. General or local depletion by bloodletting is very rarely if ever called for. Mercury as an alterative remedy, or given to “improve the secretions,” is not to be recommended. The supporting treatment is indicated in proportion to the duration of the disease and the tendency to failure of the vital powers. The diet at first should be restricted and bland, but alimentation is of course important if supporting measures be indicated. The question of irrigation does not enter into the consideration of the treatment of enteritis, inasmuch as the injected liquid does not readily ascend beyond the ileo-cæcal valve.

. Subacute and Chronic Enteritis.

Subacute enteritis is of frequent occurrence, arising either from dietetic errors or an arrest of digestion by exposure to cold, over-exertion, etc. It is not easy to distinguish, practically, cases of transient subacute enteritis from cases of functional diarrhoea; nor is it of much practical consequence to make this discrimination, since the indications for treatment in either case do not materially differ, embracing mild purgation, followed by anodyne remedies and regulation of the ingesta.

Enteritis, acute, subacute, and chronic, is described by some authors under

the name of *intestinal catarrh*. Here, as in other connections, the term *catarrh* is not adopted in this work. Authors who treat at length of intestinal *catarrh* embrace under this head cases which I describe in connection with *diarrhœa* and *intestinal dyspepsia*.

Chronic enteritis is usually referable to some prior morbid condition. It very rarely follows acute enteritis. Chronic passive congestion in the portal circulation is a cause of chronic enteritis. It may in this way attend diseases of the liver (such as *cirrhosis*), of the lungs (such as *emphysema*, *chronic pleuritis*), and of the heart (valvular lesions.) All of these affections lead to chronic intestinal inflammation by obstructing the flow of blood through the portal system. The pathological condition is at first chronic passive congestion of the intestines. Bright's disease may be accompanied by chronic enteritis. It is a frequent attendant of tuberculous ulcerations of the intestine, and it may occur in chronic tuberculosis without the presence of intestinal ulcers. Chronic enteritis occurs also as a circumscribed inflammation about other forms of intestinal ulcer, about new growths in the intestine, and above strictures of the gut. The intestinal mucous membrane in chronic enteritis is coated with mucus, and is usually of a slate or ash color from the deposition of pigment. The follicles are often enlarged and pigmented, and they may be the seat of ulcers.

The SYMPTOMS are the same as those in acute enteritis, but they are less marked. Constipation may alternate with *diarrhœa*. As regards treatment the cause should be, as far as possible, removed. This involves in many cases the treatment of a prior morbid state. [In the so-called idiopathic cases—*i. e.* cases in which the cause is not ascertainable—benefit may be derived from the alternate use of saline cathartics and intestinal antiseptics. The former deplete the vessels and empty the bowel of stagnating contents, while the latter counteract the putrefactive processes which exert so injurious an effect upon the intestinal mucosa. The best intestinal antiseptics are thymol, naphthalin, and bismuth salicylate. The diet should be limited to animal broths and tender beef, mutton, and chicken, and it is often advisable to inaugurate the treatment with an exclusive diet of skimmed milk—from three pints to two quarts daily. This, with a little toast or "*zwieback*," will support the patient, provided he be kept at rest, until it is thought advisable to give the articles above mentioned. Fatty materials should be discarded from the diet as far as possible. Astringents, such as acetate of lead, nitrate of silver, gallic acid, and the styptic salts of iron, are of little more than temporary benefit unless preceded by the course above outlined.—H.]

CHAPTER VI.

STRUCTURAL DISEASES OF THE INTESTINE.

Intestinal Ulcers.—Duodenal Ulcer.—Embolism of the Superior Mesenteric Artery.—Carcinoma of the Intestines.—Waxy Degeneration of the Intestines.—Structural Lesions causing Intestinal Obstruction.—Intussusception.—Strangulated Hernia within the Abdomen.—Rotation or Twisting of Intestine.—Compression and Stricture of the Intestine.—Obstruction from Impaction of Feces, Enteroliths, and Foreign Bodies.—Functional Obstruction.

Intestinal Ulcers.

THE important forms of intestinal ulcers are the following: simple inflammatory (including follicular), digestive, dysenteric, typhoid, tuberculous, and syphilitic. Certain rare varieties, as the embolic, the amyloid, the corrosive (from swallowing corrosive poisons), the variolous, and the mycotic (especially in malignant pustule), will receive no further attention.

Ulcers may occupy any part of the intestinal tract. In general it may be said that their favorite seats are the ileum, the cæcum, the sigmoid flexure, and the rectum. Simple inflammatory ulcers, also called catarrhal, have been treated of in connection with dysentery and with enteritis. They include follicular and non-follicular forms. Ulcers produced by pressure of impacted feces are sometimes called stercoral. Similar ulcers may be caused by foreign bodies. These ulcers from pressure are most frequent in the cæcum, vermiform appendix, and sigmoid flexure. They have been considered in connection with typhlitis (see p. 417 *et seq.*). Digestive ulcers occur only in the upper part of the intestine. They are of the same nature as digestive or simple gastric ulcer, and will be considered in the next article, under the head of Duodenal Ulcer. Dysenteric ulcers have already been described. The so-called uræmic ulcers which occur in Bright's disease, and which are sometimes attributed to the irritation of carbonate of ammonia produced from urea in the intestinal tract, are in some cases the result of a dysenteric process. Dickinson has observed small ulcers in the lower part of the ileum in connection with small contracted kidney. Typhoid ulcers will be described subsequently in connection with Typhoid Fever.

Tuberculous intestinal ulcers are very frequently present in cases of pulmonary tuberculosis. They very rarely, if ever, occur independently of tuberculous processes in the lungs. The hypothesis that the intestinal ulcers of phthisical patients are caused by swallowing tuberculous sputa is probable, in view of the fact that these ulcers have been produced by feeding animals with tuberculous substances. Tuberculous ulceration affects by preference the lower part of the small intestine. The solitary follicles and Peyer's patches are usually first involved, but tubercles may develop independently of these structures. The process often extends to the remainder of the small intestine and to the large intestine. The vermiform appendix is very often the seat of tuberculous ulceration. The solitary follicles and the individual follicles of Peyer's patches become swollen, and they undergo, first in their centre, cheesy degeneration. The cheesy mass softens and a little ulcer is produced. This ulcer extends partly by an inflammatory process, but chiefly by the development of tubercles in its edges and base. These tubercles undergo cheesy metamorphosis and softening. The shape of the ulcer may correspond at first to that of a Peyer's patch, but its tendency is to extend transversely in the course of the lymphatics and blood-vessels. This direction is explained

STRUCTURAL DISEASES OF THE INTESTINE.

the fact that the tubercles, to whose development the ulcer owes its progress chiefly in the walls of these vessels. The appearance of a fully-formed tuberculous ulcer is characteristic. Its long axis is transverse to the axis of the intestine; but this rule is not without exceptions. The ulcer may nearly encircle the lumen of the intestine. Tuberculous ulcers constitute the most frequent and important of the so-called annular or girdle ulcers. The edges of the ulcer are thickened and sinuous, and present an appearance often described as worm-eaten, from the presence of little excavations due to softened tubercles. Tuberculous granulations are usually recognized without difficulty both in the edges and in the base of the ulcer. Tubercles are developed in the vicinity of the ulcers. Patches of little white tuberculous nodules seated in the subserous tissue can generally be seen on the peritoneal surface covering the site of the tubercle. These peritoneal tubercles are of great assistance in the recognition of both the position and the nature of the ulcer. Upon microscopic examination tubercles are found in the neighborhood of the ulcer in the muscular and other coats of the intestine. They are formed chiefly in the outer sheaths of the arteries and in the lymphatic vessels. As a rule, they present the typical giant-celled structure. Woodward describes a transverse puckering of the mucous membrane in the neighborhood of tuberculous ulcers, due to a tendency in the ulcer to longitudinal contraction. Partial cicatrization of tuberculous ulcers, resulting even in stenosis, has been observed in several instances. That the tuberculous ulcers ever completely cicatrize is improbable. These ulcers do not often lead to perforation of the intestine, and very rarely indeed to general peritonitis from perforation. Circumscribed peritonitis over the seat of the ulcer is common. Tuberculous ulcers are usually accompanied by more or less inflammation of the surrounding mucous membrane. The mesenteric glands are frequently swollen and tuberculous.

Syphilitic intestinal ulcers are infrequent. In only a small number of cases has their origin from gummata been demonstrated. Syphilitic ulcers of the intestine are either round or transverse. They may form annular or girdle ulcers. Their edges are generally grayish-white, indurated, and fibrous; the base is also indurated and usually without much purulent secretion; and the serous coat over the ulcer is often thickened, and may present cicatricial tissue containing little fibrous nodules. In the thickened walls and base cheesy nodules, which are doubtless gummata, are occasionally detected. The hard fibrous tissue forming the floor and edges of the ulcer is generally dense and infiltrated with small round cells. These ulcers may be found in both the large and the small intestine. Their cicatrization leads to more or less contraction of the calibre of the intestine. Submucous gummata have been found with a without ulceration of the intestine, but they are extremely rare. They appear to be more frequent in congenital than in acquired syphilis. Syphilitic ulcers and strictures of the rectum are considered fully in works devoted to venereal diseases. According to Fournier,¹ syphilitic stricture of the rectum may be due not only to the cicatrization of ulcers, but also to a diffuse hyperplastic infiltration of the mucous and submucous coats. To this syphilitic infiltration he gives the name of ano-rectal syphiloma. Birch-Hirschfeld² has described as an occasional lesion of congenital syphilis diffuse sclerosis of the intestinal mucous membrane, which was found thickened by an infiltration of fusiform cells.

The SYMPTOMS of intestinal ulceration cannot well be considered apart from the morbid conditions on which the ulcers depend. In general, the symptoms are not characteristic of ulceration. There may be tenderness on pressure

¹ *Leçons rédigées par Ch. Porak, Paris, 1875.*

² *Wiener Med. Presse, 1878, No. 41.*

the ulceration be extensive, especially if it be seated in the large intestine. The nutrition of the patient is usually impaired. The character of the stools is often abnormal. There may be diarrhoea, with liquid and often bloody evacuations. On the other hand, constipation may be present, particularly if the ulcers be high up in the bowels. Symptoms are often referable to a coincident enteritis. The hemorrhage from intestinal ulcers may be so profuse or persistent as to prove the immediate cause of a fatal termination, but instances of this are rare. Tubercle bacilli are frequently present in the fecal discharges in cases of tuberculous ulceration of the intestines. In rare instances tuberculous ulcers of the rectum are situated so that they can be explored during life. Ulcers may give rise to perforation and fatal peritonitis. They may cause fistulous communications. If cicatrization take place, constriction of the intestinal canal may be thereby produced, and this stenosis may be the cause of death. Syphilitic ulcers are particularly likely to cause stricture of the intestine, but the same result may follow dysenteric, simple inflammatory, and even in rare instances tuberculous ulcers. Typhoid ulcers do not lead to stenosis. Not very infrequently ulcers are found unexpectedly in post-mortem examinations, there having been no symptoms referable to them during life. The prognosis depends upon the primary morbid condition. The treatment also has reference to this state. In general, the treatment indicated in chronic dysentery is applicable. Ulcers and strictures seated in the lower part of the rectum are open to inspection, and are to be treated by local applications and surgical procedures.

Duodenal Ulcer.

Chronic ulcer has the same anatomical characters in the duodenum as in the stomach, and is probably, like the latter, caused by the solvent action of the gastric juice. It is far less frequent than gastric ulcer, the proportion being as 1 to 30 of the latter. The situation is usually near the pyloric opening. In contrast with gastric ulcer the ages of patients are generally between thirty and forty, and duodenal ulcer occurs much oftener in men than in women. These are points to be taken into account in the diagnosis. The fact of its occurrence in some cases after severe burns of the skin is also to be borne in mind.

The local symptoms by which it is to be differentiated from gastric ulcer are as follows: Vomiting is often wanting, and when it occurs the intervals between its occurrence and the ingestion of food are longer. The ingestion of food does not occasion the same degree of gastric disturbance and consequent distress. Paroxysms of pain often occur having the severity and character of gastralgia. The pain, as in gastralgia, is sometimes relieved by the taking of food. The pain is referred to the right hypochondrium. Jaundice sometimes, but rarely, is associated with duodenal ulcer. From the occurrence of this symptom either duodenitis or the situation of the ulcer near the opening of the ductus communis is to be inferred. Hemorrhage is as liable to occur as in cases of gastric ulcer. Blood may be vomited, but it is passed in larger quantity by the bowels. These points relating to hemorrhage are significant as regards the diagnosis. Cancer is excluded by the absence of tumor, of the gastric symptoms usually connected with that affection, and of the appearance characteristic of the cancerous cachexia. Moreover, cancer usually occurs at a later period of life—namely, between forty and sixty years of age.

Duodenal ulcers may cicatrize, giving rise to stenosis and consequent dilatation of the stomach; but cicatrization is rare. Perforation may take place and give rise to fatal peritonitis. This result is sometimes prevented by

adhesions of the duodenum over the site of the ulcer prior to the perforation. These adhesions may take place and rupture afterward occur, as in a case which was under my observation. Duodenal like gastric ulcer may remain latent until perforation occurs.

The TREATMENT is essentially the same as in cases of gastric ulcer.

Embolism of the Superior Mesenteric Artery.

Embolism of the superior mesenteric artery is followed by hemorrhagic infarction of the small intestine. Although this artery anastomoses freely with the pancreaticoduodenal and with the inferior mesenteric, it has been shown by the experiments of Litten¹ that its branches are so little tolerant of an insufficient supply of blood that their coats undergo a molecular alteration which suffices for the production of a hemorrhagic infarction before a complete collateral circulation can be established. The wide extent of territory over which this vessel is distributed is an impediment to the rapid development of a sufficient collateral circulation, which, even in arteries more favorably situated, often requires considerable time. About thirty cases of embolism of the main trunk or of the branches of the superior mesenteric artery have been recorded. The embolus itself can usually be detected post-mortem without difficulty. The parts affected by embolism of the main trunk are the greater portion of the small intestine and the upper part of the large intestine. The extent of intestine involved of course depends upon the size of the branch obstructed. The wall of the affected portion of intestine is swollen, oedematous, and more or less infiltrated with blood. There may be in addition large and small circumscribed hemorrhages in the intestinal coats. The mucous membrane especially is swollen, soft, and infiltrated with blood. Its surface is coated with a layer of blood or of blood-stained mucus. In certain places there may be loss of substance from necrosis of the mucosa. The solitary follicles, Peyer's patches, and the mesenteric glands are frequently swollen. When the main trunk of the artery is occluded there are hemorrhages also in the mesentery. At first circumscribed peritonitis and subsequently general peritonitis result. If the artery become slowly obstructed, as by pressure, no effects follow.

The SYMPTOMS have been studied chiefly by Gerhardt and by Kussmaul. Those to which they attribute diagnostic importance are the following: 1. A source for an embolus (organic disease of the heart was usually present). 2. Abundant intestinal hemorrhages, which cannot be explained by an independent disease of the intestine or by portal obstruction. 3. Rapid fall of temperature. 4. Pain in the abdomen, often resembling colic and often violent. 5. After a time development of tympanites, and perhaps of a recognizable exudation in the peritoneal cavity. 6. The evidence of embolism of other arteries of the body. 7. In rare instances the detection by palpation of sacs containing blood between the folds of the mesentery. Vomiting was present in many of the cases reported. The bloody stools often had a fetid odor. The blood was sometimes of a tarry consistence, and at other times it was fluid or in clots. Occasionally no hemorrhage occurred. In that case the diagnosis is impossible. The symptoms develop suddenly, and death usually soon follows, preceded by collapse. It does not seem to be absolutely fatal. In a case reported by Moos which recovered the diagnosis of this affection was rendered very probable. The diagnosis in the favorable cases of Lereboullet was not so well established.

¹ *Virchow's Archiv*, 1875, Bd. 63, S. 289.

² *Würzburger medic. Zeitschrift*, 1864, Bd. 4 u. 5.

The objects of TREATMENT, as stated by Gerhardt, are to check the hemorrhage, to prevent necrotic processes in the intestine, to repair the loss of blood, and to favor the re-establishment of a collateral circulation. He says: "In what way these indications are to be best fulfilled future experience must decide." Moos treated his case which recovered by rest, lukewarm nourishing broths, small doses of wine, and by the internal and external application of ice. A certain degree of doubt necessarily attaches to the diagnosis of this case.

Embolism of the inferior mesenteric artery is sometimes unattended by symptoms; at other times symptoms similar to those described were present. Only about eight cases have been recorded.

Carcinoma of the Intestine.

Cancer of the intestine presents the same varieties as when seated in the stomach. The most frequent situation by far is the rectum. Here it is open to discovery and examination by the touch and vision. Next to the rectum, it is most frequently situated at the sigmoid flexure of the colon; and next in the transverse colon. It is situated in the duodenum or jejunum, the lower portion of the ileum, the descending colon, the ascending colon, and the middle of the ileum, as regards relative frequency in the order in which these parts are now enumerated. In these different situations it often produces obstruction by compression and stricture.

The cancerous growth, when it has reached a certain extent, if situated above the rectum, forms a tumor which may be felt through the abdominal walls. The problem is then whether or not the tumor be carcinoma. The diagnosis is to be based on the existence of radiating, lancinating pains, the age of the patient (over forty years), the frequently nodulated character of the tumor, the occurrence of bloody stools, the evidence of hereditary predisposition, and the symptoms which denote the cancerous cachexia. Fecal tumors, enteroliths, and foreign bodies are to be excluded; also, sarcomas and the benign neoplastic growths—namely, fibromas, myomas, lipomas, cysts, and adenomas. These as well as cancerous growths may produce obstruction at different situations in the intestinal canal. They cannot in cases of obstruction be excluded with certainty unless they be situated in the rectum. They cannot be differentiated from each other during life, and hence they are of pathological rather than of clinical interest. This brief reference to them, therefore, is all that is called for. Duodenal cancer is not easily differentiated from cancer of the stomach. The differentiation is not practically of importance. The association of jaundice points to the former.

Waxy Degeneration of the Intestine.

The intestine as well as the stomach is not infrequently the seat of this structural change. The alteration is generally present throughout both the large and the small intestine, but it is usually most intense in the lower part of the ileum. The mucous membrane may be the coat chiefly affected, or in addition the other coats may be involved. Usually the solitary follicles and Peyer's patches escape or are but slightly affected. In certain cases, however, the waxy change is most marked in these structures (Hayem). Neumann observed cases in which the muscularis mucosæ was predominantly affected. Waxy degeneration is not to be positively recognized post-mortem without the application of iodine or other appropriate reagents. Simple inflammation of the mucosa is generally present in cases of waxy degeneration. Kyber

denies that there is any tendency in this alteration to the production of ulcers. Tuberculous ulcerations are often present when the waxy metamorphosis is secondary to phthisis.

Waxy degeneration may be inferred when diarrhœa is a prominent and persistent symptom in connection with waxy degeneration of the liver, spleen, or kidneys, these organs being affected either singly or collectively, the latter being often the case. The lesion is rarely confined to the alimentary canal, and if so confined the diagnosis is impossible.

The lesion is a permanent one, and admits of only palliative treatment.

Certain structural affections of the intestine are important as causing mechanical obstruction to the passage of the intestinal contents. Hence, we may consider *obstruction of the bowels* or *obstipation* as caused, *first*, by structural affections; and *second*, as dependent on causes other than lesions of structure—namely, on the impaction of feces, the formation of concretions called enteroliths, the introduction of foreign bodies, and on merely functional disorder. The term ileus or iliac passion and other names have been applied to cases of obstipation with the ejection from the mouth of the intestinal contents, or so-called stercoraceous vomiting. As the latter symptom occurs in connection with obstruction from various causes, the names based upon it have no special pathological significance, and they tend to produce confusion.

Obstruction from structural affections is not of very frequent occurrence. The statistical researches by Brinton, the whole number of promiscuous necropsies being 12,000, showed obstructions from various causes, exclusive of hernia, in the proportion of 1 in 280 deaths.¹ The lesions involving obstruction are the following: Intussusception or invagination; strangulation from hernia within the abdomen; rotation of a portion of intestine upon its own axis or upon the mesentery, and twisting of a portion of intestine around another coil of intestine; compression of one portion of intestine by another portion or by a tumor situated exterior to the canal; and stricture produced by morbid growths within the canal or by the contraction following the cicatrization of ulcers. In these several affections obstipation is a common feature; but they differ in an important point—namely, certain of them causing only mechanical obstruction, and others involving in addition strangulation. This point of difference is to be taken into account with reference to diagnosis, prognosis, and treatment. The structural affections giving rise to both obstruction and strangulation will be first considered, and afterward obstruction by causes which do not occasion strangulation.

Intussusception.

Intussusception, or intestinal invagination, is the reception of one portion of the intestine into another portion. Generally, the invagination is from above downward, but in rare instances the lower portion is received into the upper. The latter, called retrograde invagination, according to Leichtenstern, never becomes incarcerated and strangulated. It is certain that invagination may occur transiently, giving rise to no symptoms. In post-mortem examinations, especially in children, innocuous invaginations of the small intestine are not infrequently found; the invaginated portion is restored without difficulty, and, aside from the displacement, there are no morbid appearances. I counted as many as fifteen such invaginations in the body of a child dead with typhoid fever. They have been observed especially after death from cerebral diseases, and they are supposed to occur

¹ *British and Foreign Medico-Chirurg. Review*, October, 1857.

during the last moments of life. It is only when the invaginated portion becomes incarcerated, giving rise to congestion, inflammation, etc., that obstruction and the symptoms of strangulation are produced. The lesion is then one of very great gravity, in the great majority of cases ending fatally. This is the most frequent of the lesions causing fatal obstruction. Of 169 cases of obstruction from various lesions collected by Phillips, 63 were of this class. An analysis of 600 cases by Brinton showed in 43 per cent. the obstruction to be from intussusception; and of 1541 cases of obstruction from all causes analyzed by Leichtenstern, 442 were due to this cause.¹ The greater relative frequency of the affection, however, relates to childhood. In adults it is less frequent than other causes of obstruction.

Intussusception brings into apposition three layers of intestine—namely, an entering, a returning, and a receiving layer. The receiving layer is called the intussusciptiens, and the middle and inner layer the intussusceptum. In the relation of the returning and receiving layers mucous surfaces are in contact, and these do not become adherent; but serous surfaces are in contact in the relation of the entering and returning layers, and inflammation, excited at the point of entrance, leads to adhesion of these surfaces extending more or less beyond this point. In this way the invagination becomes incarcerated. The vessels of the portion of the mesentery connected with the invaginated intestine are obstructed by tension. Congestion and swelling of the invaginated intestine ensue; it is dark-colored and ecchymotic, and at length it becomes gangrenous and sloughs away if life be sufficiently prolonged. The obstruction is due to the swelling from congestion and the exudation of inflammatory products. Usually, the obstruction is complete, but in rare cases the intestinal passage remains pervious although much contracted. In these cases the intussusception is usually in the large intestine. Peritonitis may extend more or less around the seat of the invagination, leading to morbid attachment to the adjacent parts.

The invagination may occur at any point in the intestinal tract. Its most frequent seat is at the junction of the ileum and the cæcum. This is shown in cases of children by the statistical researches of J. Lewis Smith.² Smith's account of the mode in which it generally occurs is as follows: "The intussusception not infrequently begins in the prolapse of the ileum through the ileo-cæcal valve, in the same way that prolapse of the rectum occurs through the sphincter ani. If death take place early, only a small portion of the ileum may have passed the valve. If the case be protracted, the tenesmus brings down more and more of the ileum with its accompanying mesentery. The constriction of the valve, which acts as a ligature, prevents the further descent of the ileum, and, the tenesmus continuing, the next step is the inversion of the caput coli, which is drawn into the colon by the descending mass, and unless the case terminate by sloughing or death the ascending and transverse portions of the colon are successively invaginated. Not infrequently the cæcum is the part primarily inverted and invaginated, and, descending along the colon, it draws after it the ileum, which sustains its natural relation to the ileo-cæcal valve. These two forms of invagination—that in which the ileum, passing through the ileo-cæcal valve, successively inverts and draws after it the caput coli and the divisions of the colon, and that in which the caput coli is primarily invaginated, and, descending along the large intestine, inverts the latter and draws after it the ileum—constitute the vast majority of cases of this disease in childhood." The invaginated portion may descend

¹ Vide *Ziemssen's Cyclopædia*, Am. ed., vol. vii.

² "Statistical Researches relative to the Seat, Symptoms, Pathological Anatomy, etc. of Intussusception in Children," *Am. Journ. of Med. Sciences*, Jan., 1862. Vide also *Smith on the Diseases of Children*.

so low as to be felt and seen at the anus, and it may even protrude from the body. The invagination, however, may occur at any point in either the large or the small intestine. Of the cases analyzed by Brinton, the intussusception was ileo-cæcal in 56 per cent., iliac in 28 per cent., jejunal in 4 per cent., and in the colon in 12 per cent. Leichtenstern's statistics of 479 cases gave 52 per cent. of ileo-cæcal and ileo-colic, 30 per cent. of iliac, and 18 per cent. of colic invaginations.

The probable causation in the majority of cases is formularized in the following quotation from Leichtenstern: "Paresis of a limited portion of the intestine, associated with vigorous peristaltic action excited by any cause whatever, offers suitable conditions for invagination." In adults the most frequent cause is a tumor of the intestine, particularly a polyp-shaped tumor, projecting within the intestinal canal. Such a tumor by its weight drags down a portion of the intestine and thus mechanically causes intussusception.

Intussusception causing obstruction and strangulation, as already stated, proves fatal in the great majority of cases; yet the affection is by no means absolutely hopeless. The manner in which recovery usually takes place is of importance in its bearing on the treatment. The invaginated portion of intestine sloughs away and is evacuated, the entering and receiving portion at the point of entrance remaining adherent and the perviousness of the canal being restored. Cases have been reported in which a large portion of invaginated intestine was thrown off, and recovery followed. Prof. Van Buren reported a case to the New York Pathological Society in which five feet of intestine were passed per anum, the patient recovering. Prof. Peaslee exhibited at a meeting of the New York Academy of Medicine, in 1865, five feet of intestine which had been passed per anum four months before the death of the patient. He also exhibited the intestines removed from the body of this patient after death. The small intestine was only sixteen feet in length, the length of the large intestine being five feet and ten inches. The invagination and sloughing had taken place in the small intestine at a distance of six feet from the duodenum. A stricture existed at this point; the intestine above was much dilated, and that below was greatly reduced in size. The patient died from inanition dependent on the stricture of the intestine.¹ Dr. William Thompson of Edinburgh collected 43 cases ending in recovery.² Of Dr. Haven's 59 cases, in 12 the invaginated portion was passed per anum, and of these 12 cases 10 ended in recovery. This is the mode of recovery which is to be hoped for after incarceration and strangulation of the invaginated intestine have taken place.

The prominent local symptoms which enter into the clinical history of intussusception are the following: Pain is more or less prominent, at first paroxysmal as in colic, and after a time becoming constant, with frequent exacerbations. The pain, if the patient be old enough to describe it, appears to emanate from a certain fixed point. Tenderness at first may not be marked, but becomes developed, being either limited to or greatest at the point whence the pain emanates. The tenderness and constant pain denote the occurrence of peritonitis at the seat of the invagination. Vomiting soon becomes a prominent and persistent symptom, with very few exceptions. The vomited matter after a time may have the odor of feces, and is then said to be stercoraceous. The accumulation of ingesta and gas above the obstruction occasions more or less abdominal distension, provided the invagination be not situated in the upper portion of the small intestine. Frequently, the accumulation of intestinal contents at the seat of the invagination gives rise

¹ Vide *Bulletin of the New York Academy of Medicine*, vol. ii. Nos. 25-29.

² Vide article on "Internal Strangulated Intestine," by Elisha Harris, M. D., in *New York Journal of Medicine*, 1853.

to a tumor appreciable by the eye and touch, and to dulness on percussion. The tumor is elongated, "sausage-shaped," corresponding to the size and direction of the dilated intestine above the seat of the obstruction. After the contents of the intestinal canal below the seat of the obstruction have been evacuated there is persisting obstipation, save in a few exceptional cases. Previously there is usually diarrhoea, followed by the discharge of bloody mucus, and if the invaginated portion of intestine descend to the rectum, tenesmus is felt and the patient is led to make straining efforts. Under these circumstances the affection is liable to be mistaken for dysentery.

The general symptoms at first may not be marked, but soon they denote a grave affection. The pulse becomes accelerated, its frequency progressively increases, and it is proportionally feeble or compressible. Progressive prostration, hiccough, coolness or coldness of the surface, and an anxious or haggard expression, denote the progress toward a fatal termination. The mode of dying is by asthenia, the pain and tenderness frequently diminishing or ceasing for some time before death.

A favorable progress is denoted by the occurrence of free evacuations from the bowels, the discharge of the invaginated portion of intestine, together with improvement in the local and in the general symptoms.

Invagination is to be distinguished from functional colic, acute peritonitis, and obstruction from other causes. The symptoms at first may denote nothing more than colic. The persistency of the pain, the development of tenderness, the acceleration of the pulse, the vomiting, etc., however, soon point to an affection of greater gravity than colic. Acute peritonitis is to be excluded by the gradual development of the local and general symptoms; by the absence of diffused tenderness over the abdomen and of rigidity of the abdominal muscles; by the localization of pain and tenderness within a circumscribed space; by stercoraceous vomiting; and by the presence of a characteristic tumor. Acute peritonitis sometimes supervenes in cases of invagination from rupture of the intestine above the obstruction. From obstruction caused by hernia within the abdomen or by rotation and twisting of the intestine the discrimination is more difficult, and, indeed, cannot be made with positiveness. The age of the patient has a bearing on the diagnosis. Invagination occurs most frequently in infancy. According to Smith's statistics, it is most liable to occur between the second and third months of infantile life. Of 47 cases, only 18 occurred between the ages of one year and twelve years. In Haven's cases the mean age was eighteen years; the youngest age was three months, and the oldest sixty-five years. In Leichtenstern's statistics half of the whole number of cases (473) occurred during the first ten years of life; and one-fourth occurred after three months and within the first year of life. Male children are somewhat more liable to it than female, the relative proportion in Smith's cases being 32 to 22, and in Haven's 59 cases 34 were males. On the other hand, hernial obstruction occurs oftener after infancy and childhood, and cases occur oftener in females than in males.

A point in diagnosis is to determine the probable seat of the invagination. The chances are that it is seated at the junction of the large and small intestine, especially in childhood. The probability of this being the seat is increased if the pain, tenderness, and swelling are situated in the neighborhood of the right iliac fossa. Tenesmus, with the discharge of blood and mucus, shows that the large intestine is involved. The invaginated portion may sometimes be felt and seen within the rectum. If seated in the small intestine, the constitutional disturbance is greater, and if the point of obstruction be toward the upper portion of the small intestine, there will be little or no abdominal distension. Indican is found in abnormal quantity in the urine

in case of intestinal obstruction from intussusception and other causes, but also in other affections of the alimentary canal.¹

The PROGNOSIS is extremely unfavorable. The usual mode of recovery the exceptional cases in which the affection does not end fatally has been stated—namely, by sloughing away of the invaginated portion of intestine, the adhesions at the point of entrance being permanent. Possibly the invaginated portion is spontaneously restored in some cases after symptoms denoting the affection are developed, but such instances must be rare; and it is also rare for the invaginated portion of intestine to remain, the canal becoming or continuing pervious. Of the 50 cases analyzed by Dr. Smith, in recovery took place, in each case by sloughing. In all these 7 cases the ages were between five and twelve years, Dr. Smith's researches being limited to cases occurring in childhood. The constitutional powers in infancy do not seem to be adequate to support the affection for a sufficient period for the sloughing process to be completed. The separation of the invaginated portion of intestine takes place, according to Leichtenstern, in the majority of cases between the eleventh and the twenty-first day. In fatal cases the duration rarely extends beyond eight days. Death may take place within twenty-four hours, the symptoms denoting "shock." In the majority of cases life is not prolonged beyond the third day. In rare instances, the obstruction being incomplete and the invaginated intestine not strangulated, the affection is tolerated for many weeks and months. There are cases, therefore, of chronic intussusception. Death sometimes is hastened by peritonitis caused by rupture of the intestine above the seat of the obstruction. In young children the duration is sometimes shortened by the occurrence of convulsions. Generally, the mode of dying is by slow asthenia.

If the existence of invagination could be ascertained prior to the development of symptoms denoting incarceration, it is probable that measures for restoration might be successfully employed; but generally a day or two elapses before the character of the affection is even suspected. In the meantime cathartics are likely to increase the invagination and diminish the practicability of restoration. The liability to the existence of this affection, especially in children, should be borne in mind in cases of apparent colic, and should dictate reserve in the employment of cathartics. As soon as the character of the affection is rendered probable by the symptoms measures to effect restoration may be tried. These measures are the injection of water or of air in considerable quantity into the rectum. If practicable, the injection should be made through a long flexible tube carried into the intestine as far as it can be made to pass without undue force. The object is to effect the restoration by the upward pressure of the air or water. The injections are not to be pushed beyond the limit at which they are borne without much suffering, and if they do not succeed after a fair trial they are not to be persisted in. They will very rarely succeed after the invaginated portion of intestine has become swollen by congestion and the peritoneal surfaces in contact have become adherent. If pushed too far, rupture of the intestine below the seat of the obstruction may be produced. I have known rupture to result from the injection successively of an alkaline carbonate and an acid, giving rise to the evolution of gas within the intestine. This method of employing pressure is highly objectionable, because the amount of pressure cannot be regulated. Cases have been repeatedly reported in which the injection of air or water has apparently effected restoration in cases of supposed invagination even after obstruction had existed for several days; but it is probable that in a certain proportion of these cases invagination did not really

¹ Vide article by Heineman, *Archives of Medicine*, New York, August, 1880.

exist. These measures for reduction are of no avail if the seat of the invagination be above the ileo-cæcal valve.

Exclusive of measures for reduction, the objects of treatment are to secure as much quietude of the intestinal canal as possible, to palliate suffering, and to support the powers of life, under the hope that sloughing and recovery may take place. The avoidance of cathartics is essential. The practitioner is not to be tempted to employ them with the hope of overcoming the obstruction. They interfere with the objects just named, and are destructive. Not only the active cathartics, but even mild purgatives and laxatives, are contra-indicated. To quiet the peristaltic movements opium is to be given in sufficient doses to secure relief of pain without inducing narcotism. Fomentations over the abdomen are useful. The strength of the patient is to be supported by concentrated and purely nutritious food given in small quantities at a time, together with alcohol. It is to be borne in mind that recovery will depend on life being sufficiently prolonged for the sloughing away of the invaginated portion of intestine. Bloodletting, counter-irritation, or any measures which tend to impair the vital forces are never indicated, and they cannot fail to do harm. After sloughing has taken place and the obstruction has been removed, purgatives are not to be employed, lest by exciting unduly peristaltic movements the adhesions at the point of the invagination may be broken up and peritonitis ensue from the escape of the contents of the intestine into the peritoneal sac.

Important practical questions relate to the operation of abdominal section, or laparotomy, in cases of invagination. Heretofore this operation has been resorted to as a last resource, and for this reason its merits were not fairly represented by its results. The first object of the operation is to restore the parts if practicable, and, if this be not practicable, a second object is to perform enterotomy and establish an artificial anus. The chances for restoration are greater in proportion as the operation is resorted to early. After strangulation has existed for some time it would not be advisable to restore the invaginated intestine, even were this practicable. After the time has elapsed for the practicability or safety of the restoration, the chances of recovery by sloughing away of the invaginated intestine are lessened by the operation, and it would have been better to have trusted to Nature's method. Taking into view this consideration, together with more or less uncertainty as regards the diagnosis, surgeons have not been disposed to regard the operation with favor, and in the early editions of this work doubts concerning its propriety were expressed. Within the past few years, however, experience has shown that laying open the peritoneal cavity is not attended with the danger formerly attributed thereto, and a number of cases have been reported in which the operation for invagination has been resorted to with success. Professor Sands, in 1877, operated successfully in the case of an infant six months old, eighteen hours after the occurrence of symptoms denoting invagination. In connection with his report of this case he gives an analysis of 20 cases collected from different sources, in 7 of which the operation was successful.¹ The important points for decision respecting the operation in individual cases are the correctness of the diagnosis and the probability or otherwise that the invaginated intestine has not become gangrenous. The probable seat of the invagination is of importance with reference to enterotomy.

¹ Vide *New York Medical Journal*, June, 1877; vide also article by Dr. John Ashhurst, Jr., in the *Amer. Journ. Med. Sciences*, July, 1874; also article by Jonathan Hutchinson, in the *London Med. Times and Gazette*, No. 29, 1873, and in the *New York Med. Record*, January 15, 1874. Peyrot has collected 23 cases, of which 9 recovered: *De l'Intervention chirurgicale dans l'Obstruction intestinale*, Paris, 1880. This work contains an analysis of 125 laparotomies for intestinal obstruction.

As a palliative measure, if the distension of the abdomen from tympanites become excessive, interfering with respiration, it has been recommended to pass an aspirating needle into the intestine and remove the gas. This procedure is not devoid of danger. Prof. Welch has met with an instance in which fatal peritonitis was thereby induced, fecal gas and thin feces escaping into the peritoneal cavity.

Reference has been already made to cases in which invagination may not involve complete obstruction and is tolerated for several months. These are, of course, cases of invagination without strangulation. A remarkable instance has been reported by Dr. C. A. Leale. The patient was a woman seventy-nine years of age. An attack of severe abdominal pain was followed by jaundice, bloody stools, tenesmus, complete fecal obstruction, and from time to time vomiting of intestinal contents. Five weeks afterward, on exploration of the rectum, an invaginated portion of intestine was felt. The finger, after considerable effort, was passed into the latter, and two quarts of pasty feces were subsequently voided. Eleven days afterward a solid body was felt at the opening of the invaginated bowel. This was broken into two pieces, and with considerable difficulty it was removed. It proved to be an enterolith four and a quarter inches in circumference and two and a half inches in length, formed by concentric layers of stercoraceous matter around a biliary calculus three and a half inches in circumference. Restoration of the bowel was speedily effected by the injection of carbonic-acid water in large quantity. This patient was seen by me in consultation.¹ Jonathan Hutchinson relates the case of a child in whom the invaginated bowel extended several inches beyond the anus. The case had been treated as one of prolapsus ani. Abdominal section was made and the bowel was restored with ease. Rapid recovery took place. The invagination in this case began at the cæcum.

Strangulated Hernia within the Abdomen—Rotation or Twisting of Intestine.

Several abnormal conditions lead to *hernia* within the abdomen. Fissures sometimes exist in the mesentery, meso-colon, omentum, and diaphragm, into which a portion of intestine passes and is liable to become incarcerated and strangulated. The vermiform appendix of the cæcum sometimes becomes adherent to an adjacent part, leaving a loop through which intestine may pass and become ligated. The same may happen in connection with diverticula of the intestinal tube, which are not very infrequent. The most frequent and important of these is that known as Meckel's diverticulum. This represents a portion of the unobliterated omphalo-mesenteric canal, by which in the embryo the umbilical vesicle communicates with the intestine. It is connected with the ileum usually from a foot to three feet above the ileo-cæcal valve. From its extremity a solid cord containing the remains of the omphalo-mesenteric vessels may pass to the umbilicus. Bands of adventitious membrane, resulting from peritonitis, may leave spaces for hernial protrusions. Various other forms of internal hernias have been described, some of which, being very rare, are to be regarded as curiosities rather than of practical importance. Much has been written concerning the so-called duodeno-jejunal hernia, of which between fifty and sixty cases have been reported. In this form of hernia, first accurately described by Treitz, the small intestine makes its way into the duodeno-jejunal fossa, which normally is a small pouch situated in front of the vertebrae at the beginning of the mesentery. A crescent-shaped fold of peritoneum, passing over the duodeno-jejunal flexure, bounds the free opening of this fossa, which is directed upward. All of the small

¹ For the report of Dr. Leale's case, vide *New York Med. Record*, November 22, 1879.

intestine has been known to push its way into this fossa, which then becomes enormously distended. The intestine lies behind the peritoneum in this form of hernia. A very rare form of internal hernia is produced by the passage of portions of the small intestine through the foramen of Winslow into the cavity of the lesser omentum. Diaphragmatic hernia is more frequent on the left than on the right side. The intestines pass more frequently through the muscular than through the tendinous part of the diaphragm, and oftener through the posterior than the anterior part. The organs usually involved in diaphragmatic hernia are, in the order of frequency, the stomach, the transverse colon, the omentum, and the small intestine. The hernia may be due to a congenital defect in the diaphragm. Acquired diaphragmatic hernia is most frequently referable to traumatism, as to a stab or gunshot wound. Rare forms of hernia which are not, strictly speaking, internal, but which are often difficult to detect by external examination, are the ischiatic, the obturator, the perineal, the lumbar. As regards the frequency of the different varieties of internal hernia, of Leichtenstern's 1541 cases, embracing obstruction from all causes, the strangulation was caused by false ligaments in 111, by the omentum in 58, by diverticulæ in 66, by the appendix vermiformis in 34, by the diaphragm in 215, and in other ways in 60. The cases collectively amount to 544.

Whatever be the mode in which the strangulation is produced, the symptoms are the same. They are, in fact, identical with the symptoms of ordinary strangulated hernia occurring at the femoral or the inguinal outlet, and they are for the most part the same as in cases of intussusception. The existence of tenesmus with bloody and mucous evacuations in certain cases of the latter constitute the chief point of distinction. Irrespective of the symptoms just named, the differential diagnosis can hardly be made with positiveness, but the chances are that in the young child invagination exists, whereas in after-life obstruction from other causes is more liable to occur. The small intestine is far more likely to be the seat of hernia within the abdomen than the large intestine. Sloughing of the strangulated portion of the intestine is destructive, whereas in cases of invagination it is the mode of cure. The only hope of recovery is in the spontaneous or operative reduction of the hernia before gangrene takes place. Distending the large intestine with air or water will probably be useless if the seat of the hernia be in the small intestine. Cathartics do harm. Opiates to palliate pain, fomentations to the abdomen, and supporting measures are indicated.

Rotation, or twisting of a portion of intestine (volvulus), so as to induce strangulation, is most liable to occur at the sigmoid flexure of the colon. An unusually small root of the sigmoid meso-colon favors torsion of this portion of the intestine. The root of the meso-colon may be contracted by cicatricial tissue from an old peritonitis. Similar contractions may occur elsewhere. Torsion may occur at the cæcum, this portion of the large intestine being exceptionally mobile. Twisting of a portion of intestine around an axis formed of mesentery or around another coil of intestine occurs in the small intestine, or a coil of intestine may become looped around the sigmoid flexure, and *vice versa*. These accidents are infrequent. Their symptoms are those of strangulation, and it is impossible to discriminate them from hernia within the abdomen. In the analysis of 600 fatal cases of obstruction from various causes exclusive of hernia, rotation or twisting of intestine occurred in 8 per cent. In Leichtenstern's 1541 cases, 54 were in this category. In cases of obstruction and strangulation exclusive of invagination the propriety of resorting to laparotomy is to be considered. Ashhurst (*op. cit.*) collected 57 cases in which this operation was performed. Of these cases, 18 terminated successfully, giving a mortality of a little over 68 per cent. It is in favor of

resorting to the operation in these cases that the prospect of recovery without it is much less than in cases of intussusception. Ashhurst's conclusion embodies a proper rule of practice in these cases. It is as follows: "In cases of acute intestinal obstruction from other causes than intussusception, should milder measures fail to give relief in the course of three, or at most four, days, laparotomy should be unhesitatingly recommended, and may under such circumstances be resorted to with a reasonable hope of success."

A highly important injunction is to be added to the consideration of obstruction dependent on the foregoing structural affections: It is, that the practitioner in all cases which present the symptoms of these affections examine carefully for inguinal or femoral hernia. The hernial tumor may be so small as not to excite the attention of the patient, and in females motives of delicacy may prevent the patient from suggesting an examination even when the presence of a tumor is known to her. Instances have repeatedly occurred of patients dying with a strangulated femoral or inguinal hernia which was overlooked, the symptoms being attributed to some inaccessible lesion or even to functional disorder.

Compression and Stricture of Intestine.

Obstruction due to closure or diminished calibre of the intestinal tube by morbid growths within the tube, the pressure of tumors situated exterior to the tube, or constriction following the cicatrization of ulcers, differs from obstruction caused by the structural affections already considered in not involving strangulation. The obstruction under these circumstances is developed gradually, having been preceded by progressively increasing constipation. Above the seat of the obstruction the intestine is dilated and filled with accumulated fecal matter. The muscular coat is hypertrophied. Below the obstruction the intestine is small, collapsed, and often atrophied. The obstruction is rarely complete. The local and constitutional symptoms incident to inflammation, sphacelation, and sloughing of the intestine are wanting. The symptoms are those arising from the gradual accumulation of the contents of the intestine above the point of obstruction. The affection progresses more slowly toward a fatal termination after the obstruction becomes nearly or quite complete than the affections which involve strangulation.

Cases of obstruction falling under this head form a considerable proportion of the cases of obstruction from all causes. Stricture of the intestine may be due to cicatrization of dysenteric, of syphilitic, of digestive, and of simple inflammatory ulcers, and in rare instances to partial cicatrization of tuberculous ulcers, to cicatrization of ulcers produced by irritant poisons, and of ulcers caused by sloughing of an invaginated portion of intestine. In exceptional cases cicatrization of unusually extensive and deep-seated typhoid ulcers may be followed by stenosis. The contraction of newly-formed connective tissue resulting from circumscribed or from general peritonitis may cause constriction of the intestine. Both benign and malignant tumors may produce intestinal stenosis, either by pressure or by invading in their growth the calibre of the intestine. The consideration of syphilitic and other strictures of the rectum belongs to surgery. In the majority of cases stricture is due to cancer of the intestines. According to the statistics of Coupland and Morris (1878), in three-fourths of the cases of stricture the seat is in either the rectum or the sigmoid flexure. The transverse and descending colon are more frequently affected than the ascending colon and the cæcum.

The discrimination of the cases of obstruction caused by compression or stricture from the cases involving strangulation can generally be made clinically by means of the differential points which have just been stated.

The fact of the obstruction being seated in the lower part of the large intestine can generally be ascertained. If seated in the rectum, it is accessible to direct exploration. If seated at the sigmoid flexure, the fact is shown by the evidence afforded by manual exploration, of distension of the transverse and ascending colon and by the inability to inject liquid beyond the rectum. *Per contra*, the situation at the upper part of the large intestine or in the small intestine is shown by the absence of distension of the large intestine with intestinal contents, and by the ability to fill the colon with injected liquid. The obstruction may be complete, but in general a certain quantity of liquefied fecal matter passes the point of obstruction and is evacuated. The injection of liquids as a means of determining the seat of stricture is open to fallacies. Not only may the obstacle be due to other causes, such as a fecal collection, but liquids may pass beyond a stricture from below, although the occlusion be complete as regards the passage downward of intestinal contents. Simon's method of exploration by the passage of the hand into the bowel may be resorted to, giving due consideration to the care to be exercised in the operation and the possible danger of producing rupture of the intestine.

The distension from accumulation of the intestinal contents may lead to rupture of the intestine. The distension may gradually go on and lead to this accident without pain or other symptoms sufficient to direct attention to the existence of any serious obstruction. This fact was illustrated by a case under my observation at Bellevue Hospital, in which nothing more than ordinary constipation had been suspected, when peritonitis suddenly became developed, ending fatally in a short time. Obstruction was produced in this case by a cancerous tumor at the sigmoid flexure; the colon and cæcum were enormously distended with feces, and the peritonitis was due to rupture of the cæcum. This case illustrates the ability of the ileo-cæcal valve to resist an amount of pressure sufficient to lead to rupture of the cæcal walls.

In the treatment of obstruction from compression or stricture active purgatives are to be avoided, but saline laxatives in small doses, in order to liquefy the intestinal contents, are indicated. Colic pains are to be relieved by opiates. The diet should be nutritious and concentrated, in order to leave as little fecal residue as possible. If the obstruction be situated at the lower part of the large intestine, careful efforts to pass a flexible tube beyond the constricted portion may be employed, and if successful liquid may be injected above the obstruction.

In cases of obstruction from compression or stricture at the lower part of the large intestine, colotomy with a view to the establishment of an artificial anus is warrantable, provided other measures to free the intestine from an amount of accumulation likely to lead to rupture be not successful. Cases have been reported in which life has been prolonged and comfortable health obtained by means of surgical interference. Cæsar Hawkins reported the results of the operation for artificial anus in 44 cases. In 10 of these cases death took place within forty-eight hours, in 21 within five weeks, and in 13 the operation was successful. Of these 13 cases, 6 died in six months, and 7 survived more than a year. Professor Erskine Mason, in connection with 6 cases in which he had performed this operation, collected and tabulated 80 cases, exclusive of the 44 cases reported by Hawkins. The reader is referred to Mason's article for a full consideration of the claims of colotomy.¹

¹ Vide *Am. Journ. of Med. Sciences*, October, 1873. A considerable number of cases has been reported in different medical journals since the date of Professor Mason's article.

Obstruction from Impaction of Feces, Gall-Stones, Enteroliths, and Foreign Bodies.

Obstipation may be produced by the causes named in the above heading, but in general they induce only more or less constipation, and in treating of the latter affection they will again be referred to. An accumulation of a mass or of masses of hardened feces sufficient to produce obstruction may take place in different parts of the large intestine. The rectum in aged persons not infrequently is the seat of such an accumulation. It is to be suspected when enemata cannot be given and perhaps the pipe of the syringe is found to penetrate a fecal mass. Examination shows the seat and the character of the obstruction. It may be necessary to break down and remove the accumulation by a scoop or the handle of a spoon. The accumulation may be at the sigmoid flexure, and then resistance to the passage of liquid injected and to the introduction of a flexible tube is found to be at that point. The accumulation may be at any point above the sigmoid flexure, but is oftenest in the cæcum or ascending colon.

Masses of feces above the sigmoid flexure may give rise to a tumor or to tumors appreciable by manual exploration through the abdominal walls. These fecal tumors are liable to be mistaken for others of a different character. A woman in the country presented an abdominal tumor of the character of which her attending physician was not satisfied, and an eminent professor of anatomy, now deceased, was requested to see the case. He was led to regard the tumor as malignant, and of course to form a very unfavorable prognosis. Shortly after the consultation a profuse diarrhoea set in, and, much to the astonishment of the patient and her physician, the tumor suddenly disappeared. It was a fecal tumor. I could cite other instances of a similar error. In view of the liability to error of diagnosis, and in order that appropriate measures of treatment may be pursued, the distinctive features of the tumors are to be borne in mind. One point in the diagnosis is their situation in the tract of the colon. Generally, they are not tender on pressure, but may be handled freely without giving pain; but to this rule there are some exceptions. By firm and continued pressure they may sometimes be moved backward or forward in the direction of the colon. By firm and continued pressure also the form of the tumor may be altered.

The absence of pain, tenderness, vomiting, and of the constitutional symptoms accompanying invagination, internal hernia, and twisting of the intestine suffices to exclude these affections, but it cannot be at once determined that the obstruction is not due to compression or stricture. The effect of measures of treatment will be likely to settle the diagnosis. The measures to be employed are mild purgatives in small doses, repeated after short intervals, conjoined with large enemata given through a stomach-tube carried upward to the sigmoid flexure. Active cathartics do not accomplish the object, and are liable to do harm. The object is to soften the harder collections, at the same time gently increasing the peristaltic movements. An emulsion of castor oil and a solution of the sulphate of magnesia or of soda are eligible purgative remedies. The bitter waters (Friedrichshall, Pulna, and Hunyadi Janos) may be found effective. The injections should consist of lukewarm water, to which syrup or mucilage should be added to obviate rapid absorption by the bowels. Some attach importance to the addition of ox-gall to the enemata. These measures, judiciously employed, will generally prove successful without much delay in relieving the obstipation and causing the fecal tumors to disappear. Mild purgatives may be required for some time after the obstruction is removed; and the treatment then will resolve itself into that adapted to habitual constipation.

Obstruction may be due to the presence of large gall-stones or of intestinal calculi or enteroliths. Gall-stones of sufficient size to produce obstruction usually escape into the intestine after fistulous communications have been formed between the gall-bladder and some part of the intestinal canal, as the duodenum. Large gall-stones may, however, pass through the greatly-distended ducts into the duodenum. Obstruction produced by gall-stones is rare, and is almost invariably situated in the small intestine.¹ Intestinal concretions or enteroliths rarely exceed in man the size of a hazelnut. In the horse and other herbivorous animals they are more common, and may attain an enormous size, weighing sometimes twenty pounds. These intestinal calculi in animals constitute a variety of the so-called bezoars, to which the formerly attributed remarkable medicinal virtues. The nucleus of these concretions in man is often formed by a gall-stone, by a hard mass of feces, or by a foreign body, as fruit-seeds, eggs of ascarides, indigestible aliment, etc. These concretions frequently present concentric layers. They are composed of the most part of phosphate of lime and of magnesia, mixed with carbonate of lime, biliary coloring matter, and intestinal mucus. Concretions occasionally form in the intestine in consequence of the prolonged use of certain mineral drugs. In this way have been formed concretions composed of calcium carbonate, of magnesium carbonate, of magnesia, and of iron. Indigestible constituents of the food, especially the fibres and husks of vegetables, may form a conglomerate mass of sufficient size to give rise to obstipation. These varieties of concretions are most frequently formed in the cæcum and large intestine. They rarely attain sufficient size to produce any considerable obstruction. They may, however, prove serious obstacles in case a stricture of the intestine already exists. These obstructing bodies may be situated within the cæcum, at the sigmoid flexure, or in the rectum. They are sometimes felt through the abdominal walls. They may lead to inflammation and perforation of the intestine, or, if not discharged and if the obstruction be complete, vomiting of so-called stercoraceous matter ensues, and death may take place from exhaustion. An intestinal concretion, cuboid in form, the vertical and transverse diameter one and a half inches, its weight ten drachms, was sent to me by Dr. O. T. Jameson, which was found after death in the ileum just above the cæcum. It was distinctly felt through the abdominal walls during life, and had existed for more than twenty years. The patient was a shoemaker, and he experienced notable inconvenience from the concretion only at times after overwork or after violent muscular exertion. He died of pneumonia at the age of forty-seven.

Finally, foreign bodies—that is, by way of distinction, bodies not contained in the aliment or derived from the body—may pass into the intestinal canal from the stomach or be introduced into the rectum. In the latter case their presence is readily ascertained by exploration, and they are removed by appropriate surgical measures. When introduced into the stomach they have been removed either deliberately, as is done by jugglers, or inadvertently. Prof. Simpson cites the case of a man who swallowed a bar of lead weighing a pound, which was removed from the stomach by an opening made through the abdominal walls, and the patient recovered. The same author refers to another case in which a large teaspoon was swallowed in a fit of delirium, and this was extracted from the ileum by the operation of enterotomy.

Small foreign bodies, not sufficient in number or not large enough to occasion obstruction, are often swallowed, especially by children. The practitioner is frequently summoned in haste, and great anxiety is felt when bodies such as the case reported by Dr. Draper, in *New York Med. Journal*, July, 1882, and case reported by Dr. Johnson, in *Medical News*, June 27, 1885.

pins, coins, portions of glass, etc. are known to have been swallowed. They may give rise to more or less irritation of the mucous membrane, and they may even occasion ulceration and perforation of the stomach or intestines. In general, however, they pass through the alimentary canal without any appreciable inconvenience, and the physician is warranted in giving assurances of the absence of danger. It is not judicious in such cases to give cathartics or laxatives. The mucous membrane is best protected against injury if a sharp-pointed or irritating body be contained in the solid contents of the bowels. Moreover, the increased peristaltic movements caused by a purgative increase the risk of injury. The desire to have anxiety relieved as quickly as possible, by ascertaining that the foreign body has passed, is an inducement to resort to purgation, which is to be resisted.

Functional Obstruction.

Persisting obstipation, accompanied with vomiting of so-called stercoraceous matter, colic pains, etc., may occur as a purely functional disorder, constituting an affection which has been called *idiopathic ileus*. A person is seized with abdominal pain, increased paroxysmally; vomiting soon takes place, and after a time the matter vomited has the odor of feces; measures to procure evacuations from the bowels are ineffectual; the pulse becomes frequent, and there is more or less prostration. After the lapse of a week or more these symptoms subside, free evacuations from the bowels ensue, and the patient recovers. These are the prominent features of a case which I reported many years ago.¹

Cases of functional obstruction may simulate those of obstruction from the structural affections which have been considered, and there is ground for the belief that in a certain proportion of the reported cases of the successful treatment of invagination² or of strangulated hernia within the abdomen the affection was purely functional. The regurgitation of the contents of the small intestine, which have a stercoraceous odor from the diffusion of the gases contained in the large intestine, in these as in other cases of obstruction, has been attributed to an inversion of the peristaltic movement. Experiments on animals do not favor this explanation. Brinton explains the regurgitation by supposing that in the centre of the intestinal tube a retrograde current is produced by the normal peristaltic movements if there be an obstruction. The obstruction, when functional, may be caused by spasmodic contraction of the tube, or it may be due to paralysis of a portion of the tube, and consequent failure of this portion to propel its contents.

The clinical discrimination of functional obstipation from obstruction caused by structural affections cannot always be made at once with confidence. The absence of tumor and of pain and tenderness localized at a particular point tends to the exclusion of the latter. The functional character of the affection may be surmised if the patient be a female subject to hysteria and suffering from the nervous symptoms associated with so-called spinal irritation. The probability of the affection being functional is increased in proportion as the obstipation, with vomiting, etc., continues, without the supervention of the symptoms which occur after sphacelation of intestine has taken place—namely, frequency and feebleness of the pulse, coldness of the surface, extreme prostration, and great tympanites; in short, the symptoms denoting impending death by asthenia.

In the TREATMENT of functional obstipation opium and other measures to relieve pain and allay spasmodic action are indicated. Cathartics may be

¹ *Buffalo Med. Journal*, 1851, vol. vii. p. 530.

² *Ibid.*, 1852, vol. vii. p. 383.

tionously tried, but if ineffectual they should not be persisted in. Enemas administered by means of a long flexible tube are to be employed. The importance of examining for the evidence of femoral and inguinal hernia is to be enjoined in connection with the subject of functional obstipation.

CHAPTER VII.

FUNCTIONAL DISEASES OF THE INTESTINE.

arrhœa.—Enterorrhœgia.—Constipation.—Intestinal Colic.—Enteralgia.—Lead Colic.—Colic from Copper.—Passage of Gall-Stones.

Diarrhœa.

THE term diarrhœa is used to denote morbid frequency of intestinal dejections which are also liquid or morbidly soft, and often otherwise altered in character. Diarrhœa is a symptom of inflammation of the large and the small intestine and of certain structural lesions, such as those incident to tuberculosis of the intestine and to typhoid fever. It is a functional affection when not dependent on inflammation or on any appreciable lesion of structure. It is an element of other functional affections—namely, sporadic cholera, intestinal indigestion, and certain cases of colic. As a functional affection it may be either transient or chronic.

Writers have described several varieties of diarrhœa, based on diversities as regards the dejections. It is sufficient to enumerate the more important of these diversities without considering each as constituting a separate variety of the affection. The following enumeration answers all practical purposes:

A diarrhœa is said to be *fecal*, *feculent*, *stercoraceous*, or *simple* when the dejections consist of the feces not changed in character, but simply morbidly soft or liquid. This form of diarrhœa is represented by the operation of cathartics, which increase the peristaltic movements and give rise to a certain amount of transudation. The dejections in this form of diarrhœa have the normal fecal odor. They are called *bilious* when, from their yellow or green color, bile is supposed to be present in larger quantity than usual. The green color which has been considered as characteristic of the action of mercury upon the liver, according to Thudichum is due to the presence of sub sulphide of mercury.¹ Robin states that the microscope shows the coloring matter to be biliverdin.² Diarrhœa is *serous* or *watery* when there is an abundant discharge of liquid; that is, when there is copious transudation or enterorrhœa. This is represented by the operation of hydragogue cathartics, such as elaterium, jalap, and the bitartrate of potassa. The dejections are called *lienteric* when they contain undigested aliment. This form of diarrhœa is met with especially in children. A diarrhœa is *mucous* or *dysenteric* when mucus is apparent in the dejections. An abnormal amount of mucus may be secreted from irritation alone without inflammation, but if the mucus be abundant it denotes an inflammatory condition. This form of diarrhœa is represented by the operation of drastic cathartics, such as croton oil. Finally, in a rare form, called *adipose* or *fatty diarrhœa*, free fat or oil in greater or

¹ *The Lancet*, Oct., 1860.

² *Sur les Humeurs*.

less abundance is found in the evacuations. This last form claims distinct consideration.

In cases of adipose or fatty diarrhœa the fat is generally liquid when passed, resembling melted butter or grease, having when cold the consistence of butter, beef tallow, or wax. In some cases it is passed in the form of globular concretions of a waxy consistency, varying in size, which melt with heat and burn like tallow. The fat is often passed by itself, and it may be passed involuntarily in a small quantity at a time. When passed with the feces it separates and collects on the surface. It has usually an extremely offensive odor. The quantity passed *per diem* in cases which have been reported varies from two or three ounces to half a pound or more.

Assuming all the fat passed from the bowels to have been ingested as fat, the rationale involves simply the non-digestion of this alimentary substance; but in some reported cases it is stated that the quantity of fat passed was not affected by the amount of fatty food. In a case reported by Wells the patient abstained for several weeks from fatty food, and as far as convenient from articles convertible into fat, without any diminution in the quantity of fat passed, nor was the latter affected by indulging freely in fatty food.¹ In two cases reported by Bright no change was produced by excluding as far as possible fatty articles from the diet. That the non-digestion of fat is in a great measure involved in the pathological explanation is, however, not to be doubted. Physiological researches have shown that the pancreatic secretion, the bile, and the intestinal juice effect the digestion of fat, and hence we are to look to the sources of these fluids in tracing the causation of fatty diarrhœa. It is an interesting fact that Bright, long before the discovery of the particular function of the pancreas by Bernard, was led by an analysis of three cases which came under his observation to consider fatty diarrhœa as a symptom of disease of the pancreas. In these three cases the only lesions found after death which were common to all were of the pancreas, duodenum, and liver. He excluded the lesions in the two latter situations because they occur in these organs so often without fatty diarrhœa; but he admits that disease of the pancreas is not always accompanied by this symptom.² The pancreas has been found diseased in a large majority of the reported fatal cases in which this organ was examined after death. Of 25 cases tabulated by Griscom,³ in 10 the bodies were examined after death; of these 10 cases, in 8 the pancreas was diseased, and in the remaining 2 cases the absence of disease of the pancreas is not stated. Yet fatty diarrhœa occurs in only a small proportion of the cases of disease of the pancreas. Thus, it was observed in only 3 of 37 cases of cancer affecting this organ tabulated by DuCosta.⁴ Hence it is to be inferred that there are generally involved morbid conditions which influence the digestion of fat, irrespective of the pancreatic secretion. Of the fatal cases among those tabulated by Griscom in which the morbid appearances were observed, the liver in several was either diseased or its ducts engorged; but in some of the cases this organ appeared to be healthy. The fact of complete recovery taking place in a certain proportion of cases goes to show that the non-digestion of fat may occur as a functional disorder.

A larger number of cases than now available is required in order to establish the clinical history, as well as the causation and pathological rela-

ons, of this form of diarrhœa. Jaundice was noted in several (six) of Griscom's cases. Diabetes mellitus coexisted in two cases. Hemorrhage from the bowels, vomiting, and pains in the abdomen sometimes resembling those caused by the passage of gall-stones, are among the symptoms noted in these cases. The duration of the affection varies much in different cases. In one case it had existed at frequent intervals for six years, in another case for two years, and in one case it disappeared after a few weeks. It is evident that the prognosis is to be based on circumstances other than the discharge of fat—namely, enlargement of the pancreas and liver, persisting jaundice, progressive emaciation, etc.; in other words, the danger depends on the lesions or morbid conditions on which the discharge of fat may be dependent or with which it is associated. Of the 25 cases collected by Griscom, 14 died, 8 recovered, and in 3 the termination was not noted.

The TREATMENT must have reference more to the circumstances connected with the fatty diarrhœa than to the latter. With our present knowledge, palliative measures according to the symptoms in individual cases, together with measures to improve digestion and invigorate the general health, comprise the treatment. In one of Griscom's cases recovery took place under the use of olive oil in large quantity, and Watson states that a case was successfully treated by Elliotson in the same way. In a case observed by Griscom at the New York Hospital the discharge of fat invariably ceased whenever the patient took from six to eight ounces of whiskey *per diem*. In the case reported by Wells, the patient, having had a daily discharge of three gills of fat for two years or more, recovered in a few weeks after giving up the occupation of a carpenter and adopting the life of a farmer.

Exclusive of the form just considered, diarrhœa involves different pathological elements—namely, increased peristaltic movements, increased transudation, increased secretion from the mucous follicles, and perhaps increased flow of bile. If the diarrhœa be purely functional, of course there is no inflammation of the mucous membrane. Practically, it is not always easy to determine whether diarrhœa be purely functional or dependent on subacute inflammation; but with reference to the treatment to determine this point is not of great importance. It is not improbable that, of the cases considered as functional in a certain proportion there is a slight grade of inflammation, such as exists in coryza or a mild bronchitis. In making the diagnosis, acute inflammation is to be excluded by the absence of diagnostic symptoms—namely, pain, tenderness, febrile movement, and anorexia. Lesions of the mucous membrane are also to be excluded. In cases of chronic diarrhœa this is not always easy. Lesions are to be suspected if the diarrhœa follow an attack of dysentery or enteritis, if it persist in spite of judicious management, if blood be sometimes present in the dejections, and if tubercles exist in the lungs. In the latter case tuberculosis of the intestine is to be suspected; and on the other hand persistent or frequently recurring diarrhœa, conjoined with cough, be the latter never so slight, should excite suspicion of pulmonary phthisis.

Transient diarrhœa due to arrested or defective intestinal digestion is of frequent occurrence. With the diarrhœa which follows over-indulgence at the table or the ingestion of certain articles of food every one is practically familiar. This is the *diarrhœa crapulosa* of the old writers. It may proceed from excesses in quantity or from particular kinds of food, the indigestibility of the latter perhaps showing an idiosyncrasy of the person affected; thus, ices, salads, shellfish, etc. in some persons always, and occasionally in all, give rise to transient diarrhœa. The undigested aliment, passing into the large intestine, having undergone chemical changes which the processes of digestion in health prevent, produces irritation and acts like a cathartic. Frequently the diarrhœa is preceded and accompanied by griping pains, and

it may be under these circumstances an element of another functional affection—namely, colic. These attacks of diarrhœa cease spontaneously, as a rule, after the expulsion of the undigested contents of the intestine, and they are rarely considered of sufficient importance to require medical advice.

An arrest of intestinal digestion may take place from causes other than errors of diet and give rise to diarrhœa. A strong mental emotion may have this effect. I was present at an operation for hernia when the surgeon, from the mental anxiety incident to his sense of responsibility, was obliged to relinquish the scalpel and precipitately retire to evacuate the bowels. A gentleman in business, receiving suddenly unexpected information which led him to know that he was a bankrupt, was immediately seized with diarrhœa. In like manner, diarrhœa may arise from an arrest of digestion from an exposure to cold or from over-exertion. In these cases the mechanism is the same as when the diarrhœa depends on dietetic errors, the undigested aliment in the large intestine acting like a cathartic.

Diarrhœa not transient, but continuing more or less, perhaps becoming chronic or recurring at short intervals, also proceeds in a large proportion of cases from indigestion. Habitual or frequent indigestion leads to diarrhœa in the same way as when it is transient—namely, the undigested aliment undergoes chemical changes and causes irritation of the large intestine. The dejections, as in transient diarrhœa, may be feculent, bilious, mucous, lenteric, or, more rarely, serous. The diarrhœa in these cases is an element or symptom of indigestion, but not infrequently, the disorder of digestion being confined to the small intestine, gastric ailments are not present. The indigestion thus giving rise to diarrhœa may be produced and kept up by various causes independent of excess or errors of diet.

It has been customary to attribute diarrhœa in certain cases to an excess or to a vitiated quality of bile. This causation is inferred when the dejections are notably bilious. This view is not improbable, although not based on positive knowledge. The bile may not be reabsorbed from the alimentary canal as in health, and hence it accumulates in excess without a morbid increase in the secretion; or it may be secreted in undue quantity or it may have a morbidly irritating property.

Diarrhœa is most liable to occur during the summer season. This may be explained, in part, by the larger proportion of fruit and vegetables in the ingesta during this season and by the effect of heat in weakening digestion. It may also in part be due to a more abundant secretion or to a lessened absorption of bile. It is a much more frequent affection in tropical than in cold or temperate climates. It occurs in travelling, especially in the summer season. Its occurrence is generally attributed to the drinking-water, but it is more rational to refer it to indigestion caused by dietetic errors, over-exertion, and disturbance of the regular habits of life. Children are far more subject to diarrhœa than adults, especially during dentition; and in children the dejections are often manifestly lenteric, showing its dependence on indigestion. It is the most prominent feature of the affection known as *cholera infantum*, or popularly, in this country, *summer complaint*. Among soldiers, especially in campaigns during the summer season or in warm climates, diarrhœa is extremely common, and is attributable to irregular habits as regards diet, conjoined with the exposure, excitement, and fatigue incident to active service. Diarrhœa occurs in persons exhausted from the want of food or from other deprivations, and in females enfeebled and anæmic from protracted lactation, due in these cases to intestinal indigestion. The same explanation probably applies to the diarrhœa which occurs at a late period in cases of pulmonary phthisis and other chronic affections when not dependent on intestinal

tinal lesions. Under these circumstances it has been called *colliquative diarrhœa*.

The accumulation of urinary principles in the blood as a consequence of renal disease occasions diarrhœa. The diarrhœa and vomiting which occur under these circumstances appear to be for the purpose of eliminating urea vicariously, and they are therefore conservative. They occur when the kidneys are removed in inferior animals, and, as shown by the experiments of Bernard and Barreswill, the liquid transudation into the alimentary canal contains either urea or the carbonate of ammonia. The dejections in uræmic diarrhœa are serous or watery.

Another pathological condition occasionally giving rise to diarrhœa is congestion of the portal vessels when the circulation in this portion of the vascular system is obstructed by hepatic disease. It thus is a symptom in some cases of cirrhosis of the liver, and it sometimes appears to limit the dropsical effusion into the peritoneal sac which belongs to the history of that disease. The diarrhœa under these circumstances is serous, transudation taking place from the pressure of the blood within the congested veins.

Crapulous diarrhœa, or transient diarrhœa due to indigestion, in general calls for little or no treatment. If the contents of the large intestine be not spontaneously expelled, an evacuant remedy may be given. A saline purgative is best adapted to this end. The propriety of this measure is to be determined by ascertaining the quantity and character of the dejections which have occurred. If these have been abundant and feculent, a cathartic is not required. If, after the bowels have been freely evacuated, diarrhœa, pain, or uneasiness continue, the irritation may be quieted by a mild anodyne; for example, a drachm or two of the camphorated tincture of opium for an adult in chalk mixture; a grain of opium; a sixth or a quarter of a grain of a salt of morphia in mint-water; or five grains of Dover's powder combined with two or three grains of aromatic powder. The remedy chosen is to be repeated after six or eight hours, if required. The diet for a day or two should be simple and somewhat restricted. Subsequently a laxative may be required if the bowels do not act spontaneously. The treatment of cases of diarrhœa tending to continuance or frequently recurring and dependent on indigestion embraces, in the first place, remedies to relieve the irritation of the large intestine. Opium in some form may be used for this purpose, but only temporarily, because its continued use tends still more to impair digestion. A mild purgative may often be prescribed with advantage, for frequent and loose dejections are not incompatible with retention of hardened feces—in fact, with constipation. The subcarbonate or the subnitrate of bismuth is an excellent remedy to relieve intestinal irritation. It is often effective, and is not open to the objections of opium. It should be given in doses of from a scruple to half a drachm to adult patients. If not effective alone, a small quantity of a salt of morphia may be added to it. Of a variety of remedies tried in cases of chronic diarrhœa among soldiers returning from the campaigns in Virginia in the summers of 1862 and 1863, bismuth, in my hands, proved the most effective, and this, I believe, was the result of the experience of others. Opiates are sometimes most effective and least objectionable when given *per os*. Pepsin or the rennet wine is sometimes useful temporarily as a means of artificial digestion, given as already recommended in cases of *dyspepsia*.

This part of the treatment, however, is merely palliative. The curative treatment embraces regulation of diet and measures to render digestion complete. The diet in quantity and quality should be adapted to the digestive powers. Chickens, eggs, and tender meats plainly cooked are most likely to be digested, but in some cases a milk and farinaceous diet is found to be

preferable. Experience in individual cases is to be the guide. Crude vegetables are to be interdicted, but ripe fruits in moderation may frequently be taken without inconvenience and with advantage. A moderate quantity of food taken at short intervals is generally advisable, rather than a full meal once or twice daily. A sea-voyage, a visit, removal from the city to the country, or the change of a warm, variable, humid, relaxing climate for an atmosphere cool, uniform, dry, and bracing, will be likely to prove highly beneficial, if not curative, in cases which resist dietetic and medicinal treatment. The efficacy of these measures is strikingly illustrated in cases of the so-called summer complaint in children.

The remedies, other than those merely palliative, which are useful in the cases of diarrhœa under consideration belong among the tonics and the astringents; and the latter may be both palliative and curative. Of the various vegetable astringents, krameria, hæmatoxylon, kino, catechu, and rubus villosus are eligible articles. The tannic acid, if well borne by the stomach, is sometimes efficient. As purely tonic remedies, quinia or the non-official preparations of calisaya-bark so much in vogue, and other bitter infusions, are often useful. Salicin, in doses of from ten to twenty grains three times daily, is an excellent tonic remedy. Preparations of iron are especially useful when the patient is anæmic, as in cases of diarrhœa occurring in females during lactation. The tincture of the chloride of iron is one of the best of the chalybeates. The persulphate or perntrate of iron is sometimes efficacious as an astringent, as well as a tonic remedy. Of mineral tonics and astringents, the acetate of lead, nitrate of silver, and the sulphate of copper have been found useful. The subcarbonate or the subnitrate of bismuth is of great value in chronic diarrhœa, not only as a palliative, but as a curative remedy, given in large doses—namely, from a scruple to a drachm three or four times daily, sometimes in combination with small doses of a salt of morphia, as recommended above in connection with palliative measures of treatment. The mineral acids are efficacious in some cases. The preparation known as Hope's mixture has been much in use. This mixture is composed of four drops of nitric acid and from forty to sixty drops of laudanum in four ounces of camphor-water, a tablespoonful to be taken every two, three, or four hours. In rebellious cases of chronic diarrhœa the various remedies which have been named are to be given in succession and in different combinations. The curative and palliative remedies are to be combined to meet the indications in individual cases.

Diarrhœa dependent on uræmia and on cirrhosis of the liver does not admit of curative treatment, and, being conservative, is only to be kept within certain limits by palliative remedies.

Enterorrhagia.

Hemorrhage into the intestinal canal is properly called enterorrhagia. The term *melæna* has been used to denote dark-colored or black dejections consisting of blood which has passed from the stomach into the intestinal canal. Partial digestion of the blood or the action upon it of the gastric and intestinal secretions renders it tarry or pitch-like in appearance and generally very offensive to the smell. Dejections of this character often follow gastrorrhagia. The term *melæna* has been also applied to cases of gastrorrhagia in which the vomited blood presents a similar appearance. Moreover, the term has been loosely applied to denote dark-colored or black evacuations not consisting of blood. The term is one of those which it is desirable should become obsolete. Cases in which blood evacuated from the bowels comes from the stomach or from any of the abdominal viscera other than the intes-

tinal canal are not cases of enterorrhagia; and cases of hemorrhoidal or other hemorrhages occurring near the anus are not properly embraced under this head. The source of the hemorrhage must be the mucous membrane between the stomach and rectum. The tarry or pitch-like appearance of blood in the stools is evidence of its source in the stomach or upper part of the intestine; but this appearance is not positive proof that the matter evacuated is blood, as a dark color may be imparted to the stools by the administration of iron or of bismuth. It probably is blood if the stools have been preceded by the vomiting of blood; but in some cases of gastrorrhagia vomiting does not take place, all the blood passing into the intestinal canal. In doubtful cases dilution in water of some of the matter evacuated renders the appearance of blood more evident, or recourse may be had to the microscope or to the spectroscope. When the source of hemorrhage is the rectum, the blood is fresh in appearance, and is passed alone, in greater or less abundance, either after a fecal evacuation or with straining efforts to procure a stool. Examination with the eye or touch will generally show the existence of hemorrhoids, but in some cases it reveals other local affections, such as ulcers, carcinoma, a polypus, or intussusception.

In cases of enterorrhagia the hemorrhage takes place in different situations along the tract of the small and large intestine. The blood is less changed in appearance the nearer its source is to the rectum and the more quickly it is evacuated. If the hemorrhage be at the upper part of the intestinal tube and if the blood pass slowly along the tube, it becomes dark or blackish, its appearance resembling that of the melænic stools in cases of gastrorrhagia, and there may be a similar difficulty in determining whether the appearance be due to the presence of blood. The quantity of blood passed varies in different cases of enterorrhagia. It is frequently large, amounting in some cases to several pints and even quarts. Evacuations may consist wholly of blood or the blood may be mixed with fecal matter. The blood may be entirely liquid or the evacuations may contain clots in greater or less abundance.

Intestinal like gastric hemorrhage has rarely any claim to be regarded as an individual affection. Like gastric hemorrhage, it is incident to a variety of morbid conditions. It is an important occasional event in typhoid fever, and will be referred to in treating of that disease. It enters into the characteristic dejections of dysentery. It is an effect also of thrombosis of the portal vein and of the mesenteric vein.¹ It is one of the symptoms of embolism of the superior mesenteric artery. It occurs in cases of carcinoma of the bowels. It is a rare occurrence in tuberculous ulceration of the small or large intestine. It belongs to the natural history of scorbutus, purpura hæmorrhagica, and yellow fever. Like gastric hemorrhage, it may be vicarious of menstruation. It is not an uncommon effect of the portal congestion occasioned by cirrhosis of the liver. It occurs, however, when not connected with these or any other discoverable morbid conditions. I have met with several examples of enterorrhagia not connected with any of the several causative conditions which exist in the larger proportion of cases. While, therefore, the chances are that some of these conditions exist, the occurrence of hemorrhage is not proof of the existence of any of them. Symptoms attributable to the loss of blood, and marked in proportion to the amount of hemorrhage, are debility, pallor, feebleness of the pulse, perspiration, sense of faintness, etc. The loss of blood may be sufficiently great and

¹ Sir William Gull has reported a case of probable thrombosis of the superior mesenteric vein and the renal veins, recovery taking place. (Vide *Guy's Hospital Reports*, vol. xlii.) Profuse intestinal hemorrhage was associated with severe pain, albuminuria, and a condition of nearly complete collapse. He cites a fatal case reported by Dr. Hilton Fagge.

rapid to occasion sudden death, but this is rare. The repetitions of the hemorrhage may lead to a degree of exhaustion and anæmia from which recovery is difficult, and a fatal result may take place by slow asthenia. In general, however, if the hemorrhage be not connected with morbid conditions which involve danger, the prognosis is favorable. Hemorrhage sufficient to occasion fatal syncope may take place and no blood be discharged by stool. In such a case the diagnosis of enterorrhagia is impracticable.

The TREATMENT of the different affections or morbid conditions with which intestinal hemorrhage is usually connected need not be here repeated. It will suffice to refer to measures having reference to the hemorrhage. These are essentially the same as in cases of gastric hemorrhage. Rest in the recumbent position and quietude of mind are important. The peristaltic movements are to be quieted by opium. Cold applications to the abdomen should be made if the arrest of the hemorrhage be urgently indicated. The most effective mode of applying cold is by means of the ice-bag. In cases in which this indication is less urgent, dry cupping, sinapisms, and warm stimulation by pediluvia will suffice without the application of cold. Food and drink should be taken cold. The diet should be restricted and bland. Purgatives are contraindicated. The mineral acids are generally thought to be useful in cases of intestinal as well as in gastric hemorrhage. The sulphuric acid lemonade has the advantage of being a grateful beverage. The various hæmostatic remedies given in cases of gastrorrhagia—namely, tannic acid, gallic acid, acetate of lead, ergot, the astringent preparations of iron, etc.—are to be resorted to in proportion to the importance of arresting the hemorrhage.

Constipation.

The terms *constipation* and *costiveness* are commonly used as synonyms denoting insufficiency of evacuations from the bowels. The latter of the two terms is sometimes used to denote a less degree of insufficiency than the former, the number of defections being normal, but the quantity deficient and the act of defecation labored. The term *obstipation* has been already defined to denote a greater amount of difficulty than constipation; that is, obstruction of the bowels, either as a functional disorder or dependent on the various lesions which have been considered in a preceding chapter. Constipation exists as a functional disorder and it is incident to various affections. As a functional disorder it is extremely frequent, and, although not a serious affection, it claims attention on account of the inconvenience which it occasions, its importance as leading to other ailments, and the difficulty often of its removal.

The affection is seated in the large intestine. The anatomical arrangements of this portion of the alimentary canal show it to be intended to serve as a temporary dépôt for fecal matter, thus providing against the need of frequent acts of defecation. The contents of the alimentary canal are propelled more slowly in the large than in the small intestine—*first*, because the circumference of the former is larger in proportion to its muscular power; *second*, in the ascending part of the colon and of the sigmoid flexure the contents are propelled in opposition to gravitation; and *third*, the liquid portion of the contents is absorbed in their passage through the small intestine. Experience shows that one free evacuation from the bowels daily is the rule in health; but this rule is not without exceptions. Some persons have, habitually, two or three evacuations daily, and on the other hand some have an evacuation regularly every second or third day without any of the inconveniences of constipation; in fact, persons of the latter habit usually experi-

ence discomfort if temporarily evacuations take place daily. In determining, then, the existence of this affection, the habit in health is of course to be taken into account. In some cases the act of defecation is delayed for one, two, or three days after the period when it should have taken place, but the evacuation when it occurs is ample. In other cases the act occurs daily, but it is incomplete, and in these cases the act is usually labored and painful, the feces being dry, compact, and hard. The affection may be occasional and transient or it may be habitual.

Constipation gives rise to various local morbid effects, such as a feeling of pressure or weight in the perineum, a sense of abdominal distension or uneasiness, flatulency, diarrhoea, and colic pains. Hemorrhoids are often attributable to this affection. It gives rise also to pain in the head, dulness of the mind, flushing of the face, palpitation, and general malaise. If the act of defecation require violent straining efforts, these sometimes occasion hemorrhage into the brain if the cerebral arteries be diseased, and hernial protrusions. The contractility of the muscular tunic of the large intestine may be permanently impaired by long-continued distension, so that the affection is necessarily permanent.

Occasional constipation is not generally considered of sufficient importance to require medical advice, and persons resort of their own accord to a purgative or an enema. It is when the affection has become habitual or chronic that cases come under the cognizance of the physician; and, in order to understand the pathological character of the affection in these cases and its causation, certain points pertaining to the function of defecation in health are to be borne in mind. In its normal condition the rectum is empty, as shown by the researches of O'Beirne.¹ This portion of the large intestine is endowed with a peculiar sensibility which in health gives notice of the presence of feces and occasions the desire to defecate. The ability to perform the act involves a certain contractile power in the large intestine, and also in the abdominal and other muscles which co-operate in the performance of the act. In habitual constipation the contractile power of the intestine is impaired by distension. The muscular tunic is more or less paralyzed from the accumulation of the intestinal contents, in the same way as the bladder becomes paralyzed from over-distension. The accumulation giving rise to the distension may be owing to the large quantity of excrement, but it is generally a result of habitual neglect of the calls of nature. The desire to defecate is resisted, or, the mind being preoccupied, is unheeded, and the act is postponed, until at length the sensibility no longer gives notice of fecal accumulation; hence the accumulation goes on, the rectum and other portions of the large intestine become distended, and paresis follows. This is the manner in which constipation as a chronic affection is produced in a large majority of cases. The hurried performance of the act of defecation, the evacuation being in consequence incomplete, has measurably the same result as the neglect of the calls of nature. Instead of receiving adequate attention as important to health, defecation is considered an annoyance to be escaped from as quickly as possible. The uncomfortable provisions for defecation, especially in the country, contribute to constipation by rendering it disagreeable to devote to the act more time than seems absolutely necessary.

Various circumstances may contribute to this affection. The abdominal muscles play an important part in the act of defecation. These muscles become weakened by obesity, and in females as a result of pregnancy. The muscular tunic of the intestine and the auxiliary voluntary muscles concerned in defecation lose more or less of their contractile power, in common with the whole muscular system, in anæmia and in other enfeebling conditions.

¹ *New Views of Defecation, etc.*, by James O'Beirne, Am. ed., 1834.

Deficiency of bile and of the intestinal secretions may enter into the causation in some cases, but probably the importance of this source of constipation has been over-estimated. Constipation is not always present when no bile enters the alimentary canal in certain cases of jaundice. Inadequate alimentation, and especially the ingestion of purely nutritious food, leaving but little excrementitious residue, contribute to constipation. Sedentary habits are supposed to favor the affection, but it is probable that other causes are generally more operative, and especially inattention to the calls of nature. On the other hand, active exercise induces constipation by rendering assimilation more active, the liquid contents of the small intestine being more fully absorbed. Loss of fluids by abundant perspiration or by diuresis is another cause. The change of habits, with, generally, an increased assimilation, incident to a sea-voyage, as is well known, induces in most cases constipation.

Occasional constipation, if slight, is relieved by a laxative pill, repeated if necessary, or by a small quantity of Epsom or Rochelle salts dissolved in a tumbler of simple or carbonated water and taken upon an empty stomach. The Congress or the Kissingen water and the stronger bitter waters—namely, the Friedrichshall, Pullna, or Hunyadi-Janos—in small doses may be taken in lieu of the salts just named. A preferable method, which will generally suffice, is to excite the action of the large intestine by a simple enema of cold water. By means of Davidson's syringe the patient can resort to this measure without any difficulty. If the constipation be more than slight, a few grains of blue mass or a purgative pill may be taken at bedtime, followed, if necessary, by a saline draught or an enema in the morning. Persons often have recourse to purgatives without consulting physicians, under an impression that such remedies are always harmless and generally useful aside from the relief of constipation. Hence it is common to take active purgatives for slight constipation, and often when nothing is required. If the constipation give rise to little or no inconvenience, it is better to wait for spontaneous relief, and a little delay will often show that medicinal interference would have been unnecessary.

The management of habitual constipation often requires much care and perseverance on the part of the physician and patient. The object is to secure regularity and sufficiency in the evacuations. The means which may be employed are various. They may be arranged into dietetical, medicinal, and mechanical. The dietetical means consist in using freely articles which leave, after digestion, a bulky residuum—namely, cabbage, lettuce, the various vegetables known in the country as greens; articles having a laxative property, such as molasses, prunes, figs, etc.; or articles with indigestible constituents which stimulate the alimentary canal—namely, bran bread, corn meal, groats, or cracked wheat. A diet consisting in part of the foregoing articles will sometimes succeed in relieving habitual constipation; but with regard to the choice of this class of means the following practical rule is to be adopted: They are not to be preferred if they disorder digestion or occasion more disturbance than medicines. More harm sometimes results from overloading the digestive organs with articles of diet difficult of digestion or subjecting the canal to the irritation of unbolted flour than the continuance of constipation would occasion. A tumbler of simple water or of carbonated water taken in the morning before breakfast is not infrequently efficacious; if not, a teaspoonful of table-salt added will often render it sufficient.

The medicinal means are laxative remedies. With regard to these, a general rule is that the remedy chosen should be mild and the quantity as small as will suffice for the object. Purgation is to be avoided. Some patients fall into the custom of allowing the constipation to continue for several days, and then

resorting to a free purgative. The constipation is of course relieved for the time, but the constipated habit becomes more and more fixed by this course. Another general rule may be stated: If more than one *small* dose of laxative be required, the remedy is to be given in small doses repeated twice or thrice daily, rather than in a single, larger dose. In this way the object is effected with a less amount of medicinal impression, and there is less risk of purgation.

As regards the particular remedy, aloes is specially suited to the desired object. It may generally with advantage be combined in a pill with a tonic, either the sulphate of quinia or a preparation of iron, and a small quantity of hyoscyamus or belladonna may be added. A very small proportion of aloes, a small fraction of a grain in each pill, will often suffice. The old preparation known as the elixir proprietatis (tincture of aloes and myrrh) is well suited to the object, a drachm given at bedtime, and repeated, if necessary, once or twice during the day. This preparation loses its disagreeable bitterness with age, and it is not generally repulsive when given with a little water and an abundance of sugar. The extract of nux vomica combined with belladonna or hyoscyamus sometimes answers well. A small piece of rhubarb taken repeatedly during the day sometimes effects the object satisfactorily, and this remedy to many persons is not disagreeable. I have known a few drops of the tincture of colchicum, repeated shortly after each meal, to answer admirably. The syrup of buckthorn, the extract of butternut, and the compound licorice powder are good laxative remedies. There are various modes of rendering the daily use of a laxative remedy not unpleasant to the taste. Prunes stewed in an infusion of senna answer well, and are not unpalatable. The confection of senna and medicated figs are also suited to persons who take a pill or potion with repugnance. Trousseau claimed for his favorite medicine, belladonna, that it acts as an efficient laxative in cases of habitual constipation. It has failed to secure this action in my experience, and I have frequently made trial of it. Here, as in other instances, experience in individual cases is to be the guide. In the majority of cases in which medicinal means are relied upon, some form of the so-called dinner-pills, or, as they have been appropriately termed, "peristaltic persuaders," will be found most convenient and satisfactory; and for the fastidious they may be silvered or sugar-coated. The white mustard-seed was formerly a popular remedy much in vogue, but this is objectionable on account of a liability to accumulate and become impacted within the intestine. Laxative remedies are not to be continued for a longer period than is required to secure an habitual action of the bowels. A minute dose of strychnia or nux vomica added to a laxative renders the operation of the latter more successful. [Probably the best internal remedy for the relief of constipation is cascara sagrada. Thirty minims of the fluid extract given at bed-time will usually secure a movement on the following morning resembling in amount and consistence the normal fecal discharge. Another method equally efficacious is to give 10 minims of the same preparation thrice daily after meals. There are various non-official elixirs of cascara, which, on account of their comparatively agreeable flavor and taste, are to be preferred in the case of children.—H.]

The mechanical means consist in the use of enemas and suppositories. The regular use of an enema of cold water at the same hour daily is a simple and sometimes an effective measure. This measure, however, is better suited to occasional than to habitual constipation. Habitually resorted to, it is likely to fail after a time; and the rectum becoming accustomed, as it were, to the stimulus of distension, it ceases to excite the peristaltic movements. In some cases a suppository of soap answers the purpose of provoking a regular and sufficient evacuation. The cocoanut butter may be used for this purpose. Common molasses candy answers equally well, an oval mass of the size of a

pigeon's egg being introduced within the rectum. This, however, is only a temporary expedient, ceasing usually to be effective after a time. [Among the mechanical methods of treating constipation is massage. In practising this method the course of the colon should be followed, the first manipulations being made in the right iliac fossa and carried upward, transversely to the left, and downward; in other words, they should follow the course pursued by the feces in their passage along the large intestine.

The best suppository for the relief of constipation is one composed of 90 per cent. of pure glycerin. It may be continued almost indefinitely without blunting the sensibility of the rectum; but all such measures should be regarded as temporary makeshifts, to be abandoned as soon as the habit of regularity of the bowel-movements is acquired.—H.]

The most important part of the management in cases of habitual constipation is not embraced in the foregoing measures. It is the adoption of a rule to solicit an evacuation at the same hour daily. The importance of this rule is to be enjoined, but of course its success will depend on the perseverance of the patient. The time of the day most convenient for the act of defecation is to be selected, and in general the most favorable time is in the morning after breakfast. At the time fixed upon the patient should devote a reasonable period to the function of defecation, but without persisting in violent fruitless efforts. This should be considered in the light of a duty, not to be omitted a single day except from necessity. It may be long before the desired object is accomplished, but sooner or later, with the aid of some of the means which have been indicated, the desire will be felt at the appointed hour, and the ability to defecate at that time will be acquired in the great majority of cases. It is impossible to secure regularity and sufficiency of the evacuations without perseverance in this part of the management. The management also includes a rule not less important—namely, never to neglect or postpone the call to defecate when it occurs either after or before the time for the habitual performance of the act of defecation. The importance of waiting for a certain period after the contents of the rectum have been expelled is to be enjoined. Often the expulsion of the contents of the rectum is immediately followed by the passage of fecal matter from the colon into the rectum, which, remaining, blunts the sensibility of the bowel and renders it accustomed to distension. The objects of the management are to be understood and kept in view—namely, 1st, To preserve or restore the normal animal sensibility of the rectum by which the presence of fecal matter is felt; and 2d, to prevent paresis from distension, and to restore the muscular power which has been lost from this cause.

If this plan were early inculcated and carried out in health, habitual constipation would be as rare as it is now frequent. The prevention is not less sure than simple. This fact should be generally understood, especially in the training of girls, most of whom become affected with habitual constipation and suffer from it all their lives. Unfortunately, the existence of the function of defecation is too often ignored from notions of false delicacy, and the affection becomes established because parents and teachers are either themselves ignorant of this simple method of prevention or consider the subject as belonging exclusively to the physician.

Cases in which the intervals between fecal evacuations are many weeks and even many months, the accumulation of intestinal contents being tolerated with more or less inconvenience during these long periods, are among the curiosities of medical experience. Of the cases in medical literature, the one in which the longest interval occurred, with a single exception, was communicated for the *American Journal of Medical Sciences* in 1874, and the autopsy, in 1876, by Dr. Thomas D. Strong of Westfield, N. Y. In this case

eight months and sixteen days elapsed without an evacuation from the bowels.¹

Intestinal Colic.

The term colic, in its etymology, relates to the colon, but it is often applied to paroxysmal, spasmodic pain in other parts. Thus, the phrase hepatic colic is used to denote the pain caused by the passage of gall-stones, and renal colic the pain caused by the passage of renal calculi along the ureter. A painful affection of the uterus is sometimes called uterine colic. In the present nomenclature of diseases there is no suffix or prefix which, joined to the name of a part, expresses a painful spasmodic affection of that part. The affection of the alimentary canal known as colic may not be seated exclusively in the colon. It is probable that the small as well as the large intestine is affected in certain cases of intestinal colic. As applied to the intestine, colic denotes pain occurring in paroxysms or in marked exacerbations, the pain being of a character supposed to indicate spasm; that is, twisting, constricting, or griping. Colic pains are symptomatic of different inflammatory affections—namely, dysentery, enteritis, peritonitis—and of the various lesions which give rise to intestinal obstruction. They also enter into the functional affection called sporadic cholera or cholera morbus. As constituting an individual malady, colic of course is independent of inflammation or structural lesions and is disconnected from any other functional affection.

An attack of colic is characterized by paroxysms or exacerbations of pain varying much in its severity in different cases. The pain is usually seated in the region of the umbilicus. It is frequently extremely severe; and the patient bends the body forward with the thighs flexed, writhes, and tries a variety of positions, groaning or crying aloud from the intensity of suffering. This severe pain continues for a few moments, and then it either ceases completely or abates, to return again with the same severity after an interval usually of brief duration. If left to continue without measures for relief, an attack may embrace a few paroxysms only or it may last for several hours. An attack lasting for a short time and ending in one or more free evacuations from the bowels is so common as to be familiar to every one.

The abdomen in attacks of colic is frequently retracted, but in some cases it is more or less tympanitic. Generally, there is absence of tenderness, and firm pressure with the hands or lying upon the belly affords relief; but in some cases there is more or less soreness and tenderness on pressure, especially over the site of the cæcum. During the paroxysms of pain the abdominal muscles are sometimes spasmodically affected, especially the rectus muscle, the sections of which are felt as hard bunches. Usually there is constipation. Nausea is sometimes present, and occasionally vomiting. The pulse is but little or not at all accelerated, and absence of fever is shown by the thermometer. The skin is cool, and during the severity of pain frequently bathed in perspiration.

In a case presenting the characters just described it is important to determine, as soon as practicable, the existence simply of a functional affection; that is, to differentiate colic from affections in which pains like those of colic occur. The diagnosis is to be made by excluding these affections. Dysentery and enteritis are to be excluded by the absence of diarrhœa and of symptoms denoting inflammation. The pain in these two affections is rarely as violent as in most cases of colic; but in cases of acute peritonitis the exacerbations of pain may equal in violence those of a severe attack of colic, and the error of confounding these two affections has been committed in not a few instances. The exclusion of peritonitis is to be based on the absence of notable tender-

¹ For synopsis of this case, vide *Clinical Medicine*, by the author, 1879, p. 354.

ness over the abdomen, of increase of temperature, of frequency of the pulse, and of other general symptoms denoting a much graver affection than colic. Invagination, internal hernia, and other obstructive lesions with strangulation cannot always be at once excluded. As a rule, the paroxysmal pain occurring in connection with these lesions at the outset, and, indeed, during a considerable time, is less violent than in colic, and after a time the existence of something more than colic is shown by persisting pain, tenderness, vomiting of so-called stercoraceous matter, sometimes tenesmus, frequency of the pulse, prostration, etc. The absence of these symptoms warrants the exclusion of obstructive lesions. The possibility that some obstructive lesion may exist is not to be lost sight of in cases which at first have the appearance of simple colic. The possibility of inguinal or femoral hernia is also to be borne in mind, and a careful examination with reference to this point is not to be omitted. The resemblance of labor-pains to those of colic is to be recollected. Pregnancy is sometimes concealed, and it has happened that the physician, supposing his patient to be suffering from colic, has been taken by surprise by the cry of a newly-born infant under the bedclothes. The passage of a urinary calculus from the kidney to the bladder may give rise to pains (renal colic) resembling that of enteralgia. This affection is to be excluded by the absence of its diagnostic features.

The several varieties of colic which writers have generally recognized do not require separate consideration. Some of these varieties rest on an insufficient basis of classification. The colic has been called *crapulous* when it proceeds from indigestion. Every one is familiar with the attacks which sometimes follow over-indulgence at the table, ending frequently in *crapulous diarrhoea*. Colic is called *flatulent* when it is accompanied with tympanites or by the expulsion of gas with relief. This variety occurs especially in infancy. The term *bilious colic* has been used when the affection is supposed to depend on hepatic derangement. This dependence is merely conjectural, and there is no more reason for continuing to append the word *bilious* to this affection than to various others in which the coexistence of disorder of the liver is equally hypothetical. Colic has been called *stercoraceous* when attributable to the retention of feces, but the latter is perhaps oftener an effect than a cause of colic. In another variety, called *verminous*, the colic is supposed to depend on the presence of worms; but it may fairly be doubted whether colic ever proceeds from this source. The variety called *saturnine* or *lead colic* is properly a distinct affection, and will be considered as such.

The morbid condition in colic is supposed to be *spasm*. Its seat is therefore the muscular tunic of the intestine. That this is the pathological character of the affection is rendered probable by the kind of pain, the constipation, together with the local symptoms, and the therapeutical measures which are found to be successful. It is not improbable, as supposed by Abercrombie, that in certain cases the spasm may be preceded by paralysis of a section of the intestinal tube, and consequent obstruction to the passage of its contents. Like other spasmodic affections, it may be produced by causes which act either directly upon the part affected or indirectly through its nervous communications.

Attacks of colic are frequently, if not generally, attributable to the local action of the ingesta. They may arise from indigestion caused by either excess in quantity or the indigestible quality of food. They not infrequently follow exposure to cold or fatiguing exertions, but these causes probably act by occasioning indigestion. Certain articles of diet—for example, shellfish in some persons—give rise to attacks of colic in consequence of an idiosyncrasy which is inexplicable. The muscular tunic of the intestine is especially susceptible to spasm in infancy, and colic occurs much oftener in early than

in middle and advanced life. A susceptibility to intestinal spasm belongs to some persons, constituting a predisposition to this affection. In the practice of every physician there are those who are subject to attacks of colic more or less frequently. This predisposition may continue for a certain number of years, and then disappear. Persons with this predisposition often have an uncomfortable sensation of weight, coldness, or numbness in the abdomen, with general languor and irritability, preceding the development of colic, and by means of these premonitions they are able to predict an impending attack.

Although attended with great and, if not efficiently treated, often protracted suffering, colic is not a dangerous affection. It may be doubted if alone it ever prove fatal. It is one of those violent functional affections from which recovery takes place rapidly. It has no tendency to eventuate in inflammation or in any other disease, but in proportion to its duration it is followed by fatigue or weakness, and more or less abdominal soreness may remain for some time.

The object of TREATMENT is the relief of spasm as indicated by the cessation of pain. Measures are to be directed to this object without reference to the cause of the attack or the existence of constipation. If, as is generally the case, an attack have been induced by the presence of irritating ingesta, measures directed to the spasm should take precedence of evacuants; and if, as is frequently the case, the bowels were constipated at the time of the attack, the removal of this condition is a secondary object. So long as pain continues there is a resistance to the action of cathartics, and to defer measures for the relief of the pain until the bowels have been evacuated is to needlessly prolong the sufferings of the patient.

In mild attacks warmth to the abdomen and extremities, a little spirit not largely diluted with hot water, some aromatic stimulant, such as anise, ginger, cloves, mint, etc., or a few drops of chloroform, will suffice to procure relief. Twenty drops of chloroform, repeated, if necessary, at short intervals, will sometimes afford prompt relief in severe cases; if not, opium in some form is to be given to the extent of procuring freedom from pain. Administration *per enema* is to be preferred. A drachm of laudanum, with the same quantity of the tincture of asafoetida in a small quantity of mucilage or starch, may be injected, with injunctions to the patient to resist the desire to expel it; and usually in a short time this desire passes off. If complete relief do not follow in the space of an hour, the enema may be repeated. If the suffering be extremely intense, double this quantity of laudanum in the case of an adult may be given in the first or second enema, or a solution of a salt of morphia may be injected hypodermically. If necessary, the enema or the hypodermic injection may be repeated a second or third time. A similar plan is to be pursued as regards the doses and repetitions if the opiate be given by the mouth. If hypodermic injections be given, caution is to be exercised in their repetition. Fatal narcotism has been induced by want of caution in this regard. Hot fomentations or dry heat should be applied to the abdomen. Speedy success may be counted upon by pursuing this plan of treatment.

The subsequent treatment is to be determined by circumstances relating to the abdomen. If no inconvenience be felt, measures to effect a movement of the bowels need not be employed for twenty-four or even forty-eight hours. Not infrequently, if the physician be not in haste to give a cathartic, a sufficient evacuation occurs spontaneously. If measures to effect a movement be required, a large simple enema may suffice; if not, a mild saline purgative may be given in divided doses, or castor oil if this remedy be not offensive to the patient. The diet for a day or two should be simple and restricted.

The certainty with which colic yields to an efficient opiate treatment renders it one of the affections which exemplify very palpably the resources of medicine. Some patients, however, suffer considerably from the after-effect of the opium given, and this in a measure compromises the mutual satisfaction of the physician and patient in the success of the treatment. Persons who are unfortunately affected unpleasantly by most forms of opium are sometimes able to take certain preparations with less inconvenience than others. The experience of the patient on this point should be consulted.

Enteralgia.

The term enteralgia denotes a neuralgic affection referable to the intestine. It has to the latter the same relation as gastralgia to the stomach. Gastralgia and enteralgia may be associated (gastro-enteralgia). Enteralgia and colic are not infrequently confounded; and it is not always easy to distinguish, clinically, the one from the other. Enteralgia is characterized by pain within the abdomen, with intermissions or remissions, the pain having more or less intensity, but lacking the twisting or griping character of the pain in colic. It can be so severe as to lead to contortions and oral expressions of suffering. In females enteralgia is an element of attacks of tympanites due to the formation of gas, and is often associated with hysterical phenomena.

The DIAGNOSIS involves the exclusion of the various affections from which colic is to be discriminated, and the exclusion of the latter affection. (Vide p. 457.) The so-called rheumatism of the abdominal walls (myalgia) is also to be excluded. Lumbo-abdominal neuralgia is to be discriminated by the existence of tenderness in front at the umbilical or hypogastric region, and also at the points in the lumbar and lateral portions of the body, whereas in enteralgia, tenderness on pressure is generally wanting. Moreover, this affection, as well as myalgia, is generally unilateral.

The TREATMENT involves the same principles as the treatment of gastralgia and other neuralgic affections. (Vide p. 385.)

Lead Colic—Enteralgia from Lead.

The affection now commonly known as saturnine or lead colic has been described by writers at different times and places under a variety of names: Painter's colic, plumber's colic, colic of Poitou, colica pictorum, Devot's colic, colic of Madrid, rachialgia, dry bellyache, and other names might be added, all relate to the same affection, which is one of the forms under which lead-poisoning is manifested. The affection differs from ordinary colic as regards not only its causation and clinical history, but its pathological character. It is not a spasmodic, but a neuralgic affection, a variety of enteralgia.

It is developed usually in a gradual manner, and is preceded by prodromic phenomena which are the general effects of lead-poisoning—namely, pallor due to anæmia, and frequently an icterode hue of the skin, a peculiar odor of the breath, and a metallic taste in the mouth, loss of appetite, coldness of the limbs, more or less emaciation, and muscular debility. The pain in the abdomen, at first comparatively slight, progressively increases in length the chief ailment. The pain is oftenest referred to the umbilicus, sometimes, however, to the epigastrium or hypogastrium; it may be limited to other situations or it may extend over the whole abdomen, but it is usually confined within a small space. The pain is sometimes referred to the back, the genital organs, and in other directions.

At other times acute and lancinating.

different cases within wide limits as regards intensity. In a mild form it merely occasions annoyance, like the pain in certain cases of gastralgia, but in a severe form the suffering is extreme, causing the patient to assume a variety of unnatural and fantastic positions, and to utter loud groans or cries as in severe cases of gastralgia and ordinary colic. The abdomen may be more or less meteorized or tympanitic, but it is oftener depressed and resisting to pressure. The resistance to pressure is caused by tonic contraction of the abdominal muscles, and this in some cases is a marked feature of the affection. Pressure on the abdomen, if made gradually and over a considerable space, is generally well borne, and often affords relief. Patients are inclined to lie upon the belly with a folded pillow or some other substance, and sometimes the closed hand, placed under them over the seat of pain. Pressure, however, with the ends of the fingers or percussion of the abdomen may not be well borne. The bowels are constipated, the exceptions to this rule being infrequent, and the dejections frequently consist of small hard lumps, or scybala. More or less nausea occurs in a majority of cases, and not infrequently vomiting. Hiccough and eructations of gas are not uncommon. The appetite is lost. The urine is scanty and micturition is sometimes difficult and painful. Circumscribed projections or tumors, changing their situation, and due, evidently, to an accumulation of gas in a portion of the intestinal tube, have been observed. The pain may be exclusively in paroxysms, the patient in the intermissions being entirely free from it, but much oftener more or less constant pain is experienced, with exacerbations. The paroxysms or exacerbations vary much in different cases in duration as well as severity. They may last for a few moments only or continue for several hours. The intermissions or remissions also vary in duration from a few moments to hours and even days.

In conjunction with the foregoing local symptoms there is no fever unless there be some accidental complication. The pulse is abnormally slow and frequently irregular. It is generally fuller and harder than in health. The skin is cool. The mind is anxious and depressed. The strength fails in proportion to the severity of the pain and the duration of the affection. The affection may be complicated with other manifestations of lead-poisoning—namely, paralysis affecting certain of the voluntary muscles, especially the extensors of the forearm, amaurosis, neuralgia in different situations, occasionally epileptiform convulsions, delirium, and coma. The latter have been embraced by Tanquerel and other writers under the name of lead encephalopathy.

The affection has no definite duration, in this respect resembling neuralgic affections in general. When left to itself it may end in a few days or after the lapse of weeks, and if the patient continue to be exposed to the cause it may persist for an indefinite period. In itself it involves little or no danger to life, nor is there ground to believe that it leads to any serious abdominal disease; but other effects of lead-poisoning which may complicate or follow this affection, especially the effects embraced under the name of lead encephalopathy, are liable to end fatally. The affection frequently pursues an irregular course, varying in severity much at different periods; and relapses, after all the symptoms have ceased for days or weeks, without any fresh introduction of lead, are not uncommon.

R. Maier found in rabbits poisoned with small doses of lead degeneration and atrophy of the ganglion-cells in the intestinal wall and increase of connective tissue in the ganglia. He and Kussmaul had previously found in a case of lead-poisoning in a human being a sclerosis of the coeliac ganglia. It is probable that lead acts directly upon the sympathetic ganglia in the intestinal wall, causing sclerosis and partial necrosis of these structures.

FUNCTIONAL DISEASES OF THE INTESTINE.

the introduction of lead into the system in sufficient quantity to give rise to its morbid effects may take place through the lungs, the stomach, the mucous membrane in other parts, and the skin. Certain occupations involve inhalation of lead. Persons employed in the manufacture of lead paints are most exposed, and of those who suffer from lead-poisoning the largest proportion are of this occupation. Next to this class, painters are most exposed. More or less exposure by inhalation belongs to a great number of occupations, such as paper-staining, grinding of colors, glazing cards, manufacturing earthen pottery, plumbing, shot-making, etc. Lead-poisoning has repeatedly occurred from sleeping in newly-painted rooms. Lead may be introduced through the stomach in various articles of food and drink. The colic of Poitou was due to wine, and that of Devonshire to cider adulterated with lead in order to give it sweetness. This kind of adulteration has been practised since the occurrence of the affection in the places just named, and it perhaps still sometimes resorted to. Liquid and solid articles of diet, especially if they contain a free acid, become impregnated with lead by being in leaden vessels or earthen vessels glazed with lead. Some years ago a large number of persons within a limited district in Ohio were affected with a disease which for some time was regarded as a novel epidemic, and was called dry cholera. It was found to have the diagnostic characters of lead colic, and was traced to the common use of a cheap kind of earthenware made in the vicinity, into the glazing of which lead entered. An epidemic colic in New Orleans was traced to lead contained in soda-water; and Prof. Doremus some years ago demonstrated the presence of lead in considerable quantity in soda-water drawn from fountains in this city (New York). Water distributed in lead pipes is not infrequently the vehicle of its introduction into the system.¹ Lead sometimes enters into the substances used to color confectionery, condiments, and other articles in sufficient quantity to give rise to poisonous effects. Articles enclosed in lead-foil may become contaminated. Authentic instances of poisoning by the use of tobacco thus enclosed have been reported, and in France enclosing tobacco in lead is prohibited by law. The habit of chewing shot and pieces of the lining of tea-boxes has been known to give rise to various manifestations of lead-poisoning lasting for years before the cause of disease was discovered.² During the spring of 1866 two hundred and thirteen cases of lead-poisoning occurred in the Walkill Valley, Orange Co., New York. After considerable research it was ascertained that lead was contained in the flour and meal used in that part of the country. The source of the lead was ascertained to be the stones used for grinding the meal and flour. The stones were old, constantly needing repair, large cavities frequently occurring, which instead of being filled up with cement were filled with common lead. Attrition of the grinding detached minute particles of lead, and the lead becoming mixed with the flour and meal was transformed into the carbonate by the process of fermentation and baking.³ [Another cause of lead-poisoning is the lead chromate (chrome yellow) sometimes used by ignorant unscrupulous bakers as a cake-dye. Dr. David D. Stewart of Philadelphia in 1887 traced sixty-four cases of the disease to this source.—H.] It may be poisoned by sucking leaden toys, glazed writing-cards, painted nipples, etc. These are only a few of the diverse modes in which lead finds its way into the alimentary canal. The use of lead as a remedy has given

News, June 18 and Dec. 21, 1887.

colic and other morbid effects. It may be introduced through the skin, although doubtless with difficulty. Lead-poisoning is sometimes attributable to the long-continued application, to the hands and face, of a cosmetic containing lead. I have known a case in which phenomena denoting lead-poisoning were attributable to the use for a long period of a dressing for the hair containing the acetate of lead. Finally, instances of lead-poisoning by means of collyria and vaginal injections have been reported.

The DIAGNOSIS of lead colic in most cases is not difficult. If the occupation of the patient involve obvious exposure to lead, a suspicion of the nature of the affection is of course at once aroused; but this and other manifestations of lead-poisoning not infrequently occur in persons who are not aware of any such exposure, and it may require no small pains to discover the mode in which the poisoning has taken place after the character of the affection has been ascertained. The diagnostic characters of lead colic as compared with those of ordinary colic offer points of difference which enable the physician to discriminate it from the latter. The gradual development, the occurrence of remissions much more frequently than intermissions, the persistency of the affection, the concurrence of pain in the back, limbs, and sometimes in the chest, the occurrence of nausea and vomiting, the obstinacy of the constipation, and frequently dysuria, characterize this affection when contrasted with ordinary colic. Coexisting paralysis in some cases, especially if limited to the extensor muscles of the forearm, confirms the diagnosis. Enteritis and peritonitis are excluded by the absence of symptoms denoting inflammation. Enteralgia, exclusive of its occurrence in connection with hysteria, is so rare, except when produced by lead, that its existence is strong presumptive evidence of this causation. A valuable sign is a blue discoloration of the gums at their junction with the teeth. The blue line on the gums may be apparent on the upper or lower jaw or on both. It is wanting in sections where teeth have been lost. It is most marked in proportion as the teeth are encrusted with tartar and in persons who neglect cleanliness in this situation. The discoloration is attributed to the formation of the sulphide of lead, sulphuretted hydrogen being evolved from the decomposition of particles of food remaining between the teeth and beneath the margin of the gums. The lead may be introduced through the mouth either with the inspired air or in food or drink, or sufficient lead may be eliminated in this situation to account for the sign. The sign is not present in all cases. Its absence, therefore, is not proof that lead colic does not exist. Clinical observation, however, shows that the sign is present in a large majority of cases. It is found frequently to precede the development of colic and other affections dependent on lead-poisoning. It is not a transient sign, but is likely to persist, not only during the continuance of the affection, but for some time afterward. In a diagnostic point of view it is highly important, and the gums should be examined with reference to it whenever lead-poisoning is suspected. A chemical analysis of the urine may show the presence of lead in this fluid. In a case in which the lead was introduced by the use of a cosmetic called "the bloom of youth," lead was obtained from the urine in sufficient quantity to form distinct particles of the metal.¹ Edes states that if the iodide of potassium be given for a few days before an examination of the urine, and the metal be not then found, it is safe to exclude plumbism from the diagnosis.²

The TREATMENT of lead colic embraces palliative and curative measures. The pain is to be palliated by anodynes given by the mouth or rectum, conjoined with soothing applications to the abdomen, as in cases of ordinary

¹ For the method of testing the urine for the presence of lead employed by Prof. Doremus, vide my work on *Clinical Medicine*, 1879.

² Vide *Therapeutic Handbook*.

colic. Chloroform given by the mouth and applied over the abdomen acts promptly and efficiently in relieving the pain. If this is ineffectual, opium in some form is required, the doses and their repetition graduated by the intensity and persistence of the pain. Relief may be obtained by free purgation, and for this end saline or such other cathartic as the stomach will best tolerate may be given, and their operation aided by purgative enemata. The obstinacy of the constipation often renders it difficult to procure free evacuations from the bowels, and active cathartics may be required. The employment of cathartics may be useful in removing the contents of the alimentary canal. Aside from this and the relief of inconvenience from constipation, cathartics are not indicated in Croton oil and other drastic cathartics, heretofore entering into the treatment of this affection, are contraindicated. The warm bath is useful as a sedative, soothing measure.

Several remedies have been supposed to have a curative efficacy in lead colic. Alum is one of these. Brachet, in a prize essay on the treatment of lead colic, stated that he had treated 150 patients with this remedy more successfully than by opium and purgatives. From one to two drachms of alum were administered during the day in a ptisan to which 40 or 50 drops of laudanum were added, a mild aperient given on the third day, and alum continued for two or three days after the symptoms of the colic had disappeared. Other observers have not met with a similar success in the alum treatment. Sulphuric acid has been advocated on the basis of its success in a large number of cases. A drachm of dilute sulphuric acid in a quart of sweetened water forms a pleasant drink resembling lemonade; this may be taken in the twenty-four hours. Tanquerel denied the efficacy of this remedy, giving as the basis of his denial the results of its use in 100 cases. The prophylactic efficacy of the sulphuric-acid lemonade has, however, been satisfactorily proven in the lead-works at Birmingham. Strychnia or nux vomica has been recommended as a curative remedy in lead colic, and nitrite of amyl have been used with some benefit in lead colic. The use of these is based upon the view that the colic is due to spasm of smooth muscles, either of the intestine or of blood-vessels.

The remedy now regarded as possessing the most efficacy is the iodide of potassium. Its use in the treatment of lead diseases, and also in the treatment of the presence of mercury in the system, dates from the publication of a paper by Melsens.² Assuming that the local manifestations of lead poisoning are due to the presence of an insoluble compound of lead in the tissues of the affected parts, Melsens claims for the iodide of potassium the power of effecting the liberation of the lead and its elimination from the system. The iodide is supposed to combine with the lead in the system, forming the soluble iodide of lead, which passes out of the body in the urine. Chemical examination of the intestine, the paralyzed voluntary muscles, and other organs in cases of lead-poisoning has shown the presence of a larger quantity than is to be accounted for on the supposition that no lead exists in the body in health. The examination of the urine in cases of lead-poisoning under treatment with the iodide of potassium has shown the presence of lead, its absence in this liquid having been ascertained before the treatment.³ Finally, clinical observation appears to afford pro

² *Annales de Chimie et de Physique*, 1849; also, *British and Foreign Medical Review*, 1853.

³ For facts verifying this statement, see a report of the results of treatment with the iodide of potassium in 23 cases in the New York Hospital by H. S. S. in the *New York Medical Times*, February, 1854.

efficacy of this treatment. With reference to the therapeutics of this affection, knowledge of its natural history as regards termination when left to its own course is important. Tanquerel in his valuable treatise gave the results in 31 cases in which no treatment was pursued for twelve days after admission into hospital, the affection having existed for one or more days before admission. Of 8 of these cases in which the colic was violent, in 3 a spontaneous cure took place within the twelve days—namely, on the third, eighth, and eleventh day. Of 13 cases in which the colic was of moderate severity, in 5 a spontaneous cure took place on the fourth, seventh, eighth, ninth, eleventh day, and in 1 on the thirteenth day. Of 10 cases in which the colic was light, in 6 a spontaneous cure took place within the twelve days.

In the treatment of lead-poisoning by the iodide of potassium Melsens enjoins to begin with moderate doses and to increase the doses gradually. He supposes that disturbance may arise from dissolving the lead out of the tissues rapidly. Five grains may be given three times daily at first, and the quantity increased to a drachm *per diem* if the remedy occasion no inconvenience.

The utility of the warm bath as a palliative measure has been already referred to. It may be useful in promoting the elimination of lead through the skin. It is useful by removing from the skin lead which comes into contact with, and adheres to, the surface in persons engaged in certain occupations. The sulphur bath may be employed for the latter object. This is made by adding four ounces of the sulphide of potassium to thirty gallons of water in a wooden bathing-vessel. The use of this bath renders the presence of lead on the skin apparent by the production of a dark discoloration which is readily removed by a brush. The blackness is marked in various parts of the body in painters and workmen employed in the manufacture of the preparations of lead used as paints, especially if they have neglected cleanliness; but it may be due to the presence of lead eliminated from the body and remaining adherent to the surface. The bath renders the lead which may be in contact with the skin inert, and it is useful as affording evidence that the surface of the body is entirely free from lead, whether derived from without or eliminated.

Prevention of the continued introduction of lead into the system is an essential part of the management. The occupation is to be suspended if it involve exposure; and if the affection be renewed or there be other manifestations of poisoning on resuming the occupation, it should be exchanged for some other. If the source of the poisoning be not apparent, it is to be sought for until found. This poison is one which gives no notice of its entrance into the body, and no manifestations of its presence until a certain amount of accumulation has taken place. The affection under consideration is but one, although the most frequent, of the forms of disease to which the poison gives rise. There is reason to think that obscure and indefinite ailments are not infrequently produced by it in cases in which suspicion of the cause is not awakened; and the liability to these as well as the more marked effects from the use of water conducted in lead pipes and various other sources, some of which have been enumerated, is one of the important subjects pertaining to public health.

The protection of those necessarily exposed to an atmosphere more or less charged with lead or to contact with it is also an important subject. Much may be done to prevent its introduction by attention to ventilation, clothing, baths, washing the mouth, and the occasional use of purgatives. Special means of protection, such as the application of moist sponges to the mouth and nostrils or the use of masks, under certain circumstances may be important.

After recovery from the colic an anæmic condition, with general debility, will often claim appropriate medicinal and hygienic measures of treatment.

Colic from Copper.

Writers have described a form of colic supposed to be produced by the introduction and accumulation of copper in the system, and the term *metallic colic* has been used to embrace not only the colic due to lead, but abdominal pains with other symptoms attributed to copper, mercury, and arsenic. The diagnostic features of so-called copper colic, as contrasted with lead colic, have been considered to be as follows: Limitation of pain to the abdomen, increase of pain by pressure, enlargement more frequently than retraction of the abdomen, and diarrhoea with greenish stools. These symptoms denote not merely functional disorder, but gastro-enteric inflammation. An extended and careful examination of a number of establishments in which the workmen were exposed to emanations from, and contact with, copper in various modes, conducted by Chevallier and Boys de Loury in Paris, led to the conclusion that such an affection as colic from copper does not exist.¹ This conclusion, however, is by no means inconsistent with the fact that copper within the system exerts a deleterious effect. Arsenic and preparations of mercury, taken in quantities sufficient to produce the phenomena of a local acrid or irritant poison, give rise to pains which may resemble those of colic. Accumulating within the system, these minerals occasion certain toxic effects; but they do not under these circumstances lead to abdominal symptoms which may with propriety be considered as an individual affection under the name of colic.

Passage of Gall-Stones—Hepatic Colic.

The passage of biliary calculi along the cystic and common bile-duct may give rise to symptoms resembling those of acute gastralgia. The discrimination at once is not always easy. Moreover, a paroxysm of pain from the passage of a gall-stone, or hepatic colic, is to be discriminated from affections other than gastralgia—namely, peritonitis, ordinary colic, colic with intestinal obstruction, acute gastritis, and the passage of calculi from the kidney to the bladder. Biliary calculi usually form in the gall-bladder, but they have been found in the hepatic duct and its branches within the liver. They vary in size from that of a pin's head to that of a hen's egg. They are frequently found in the gall-bladder after death, sometimes in great number. A collection of several hundred is not uncommon. Bennett relates a case in which the number amounted to two thousand, and cases have been reported in which the number was still greater. They are usually of soft consistence and of low specific gravity. They are sometimes white, but oftener either of a yellow, brown, or greenish color from the imbibition of bile. On section they are often found to consist of successive layers which differ in consistence and color. In general they are composed chiefly of cholesterin, but they frequently contain the salts of lime. Remaining within the gall-bladder, they may occasion no inconvenience; but if many or large, they may give trouble by distending the gall-bladder, and they may lead to ulceration and perforation. If the perforation be into the peritoneal sac, diffuse peritonitis follows, and will be likely to prove fatal. If the distended gall-bladder become adherent to the abdominal walls, the perforation may lead to circumscribed abscess which opens externally, and a number of calculi may be discharged through the fistulous opening.² They are oftener discharged by an ulcerated opening into the intestinal canal. The opening may take place

¹ Vide Nysten's *Dictionnaire de Médecine*, etc., 1858; also Valleix, *op. cit.*, tom. v.

² For an account of reported cases, and also cases of cholecystotomy, vide article by Dr. G. W. H. Kemper, in *Transactions of the Indiana State Medical Society*, 1879.

into the duodenum or colon. It has been known to take place into the stomach, the portal vein, and the pelvis of the kidney. Gall-stones sometimes occasion a noise like that produced by the collision of nuts or marbles in a bag when shaken if forcible pressure or strong percussion be made over the distended gall-bladder; but in general their existence is not suspected until, having entered the cystic or common duct, they occasion, by their passage toward the intestine, paroxysms of so-called hepatic or gall-stone colic. It is evident that the time occupied in the passage of a gall-stone, as well as the suffering, will depend, other things being equal, on its size and the irregularity of its shape.

The pain occasioned by the passage of a gall-stone is frequently abruptly developed without any obvious cause, but in some cases it is preceded by a sense of uneasiness referred to the right hypochondrium. In the majority of cases the attack occurs three or four hours after a meal. The suffering is often extreme, causing the patient to writhe and assume a variety of positions with the hope of obtaining relief. The pain is referred to the epigastrium or the right hypochondrium. It may radiate thence throughout the abdomen, often extending into the chest and to the right shoulder. Usually, there is more or less tenderness over the seat of the pain, but in some cases pressure affords a certain measure of relief. Vomiting speedily occurs in the majority of cases, and is repeated more or less frequently during the continuance of the pain. The bowels are constipated. The pulse, as a rule, is not accelerated, and it may be retarded. Not infrequently it becomes small and weak. The retardation of the pulse is sometimes notably great. I have known it to fall to 30 and to 20 beats per minute. Pallor of the face and coldness of the surface are marked in some cases. Chilly sensations, with rigor, are not uncommon. The duration of the paroxysm is variable. It may last for a few moments only or for many hours or days, depending of course on the period occupied by the passage of the stone either onward into the intestine or backward into the gall-bladder. At length the pain and other symptoms suddenly cease, and nothing remains but more or less soreness and the fatigue occasioned by the suffering. If the paroxysm have been of considerable duration, the urine may show the presence of bile, and jaundice is frequently produced. These symptoms disappear after the paroxysm is ended. The dejections may show deficiency or absence of bile. The absorption of bile and its absence in the stools show that the gall-stone is impacted in the common (not the cystic) duct, and that its form and size are sufficient to cause obstruction more or less complete. Under these circumstances the bile may accumulate within the gall-bladder, and distend it so that it can be perceived by the touch below the lower margin of the liver. Finally, after the paroxysm is ended one or more gall-stones may be discovered in the dejections if these be carefully examined for several successive days. In some cases, however, careful examinations of the feces fail to show the presence of a calculus or of calculi. The failure to discover them is not proof that an attack is not one of hepatic colic. The gall-stones in these cases, after remaining for a time in the cystic duct, may have passed backward into the gall-bladder, notwithstanding the valvular folds of the lining membrane. Another explanation is that the cause of the obstruction is inspissated bile, and not properly gall-stones.¹

After an attack of hepatic colic recurrences are to be expected, but as regards the intervals cases differ greatly. Successive attacks may occur after days, weeks, months, or years. Not infrequently a greater or less number of attacks follow in quick succession—several perhaps occurring on the same

¹ The presence of inspissated bile in the dejections may be ascertained by chemical tests. (Vide Bartholow in *System of Medicine*, by American Authors, vol. ii. p. 1073.)

day and for several days in succession. This is probably owing to porary dilatation of the cystic and common duct produced by the passage of calculi of considerable size, in consequence of which other stones with gall-bladder more readily escape. The patient under these circumstances may be consoled by the reflection that the more frequent the passage of the less the number that remains to give rise to subsequent attacks. The frequent repetition of attacks, if severe, may occasion considerable disturbance of the digestive system and general prostration. A single instance of this during a paroxysm has come under my observation.

The differential diagnosis of the passage of gall-stones from acute peritonitis is to be based on the following points: The occurrence of pain not caused by any obvious dietetic or other cause; the prominence of vomiting as a symptom; the presence generally of more or less tenderness; the existence of bile in the urine, and of icterus or an icteroid hue of the conjunctiva and skin; retardation of the pulse; the persistence of pain notwithstanding opiates are given in full doses; the sudden relief occurring irrespective of remedies; and after the attack the discovery of biliary calculi in the evacuations.

The examination of the evacuations for gall-stones not only serves to confirm the diagnosis, but on the appearance of the stone or stones may be elicited an opinion that the gall-bladder either does or does not contain stones which have not escaped. If only a single round or oval stone be discovered it is probable that this was a solitary calculus in the gall-bladder, and further attacks need not be expected; but if several stones be discovered, pedunculated in form, with smooth or polished facets, which may be plane, convex or concave, it is highly probable that the gall-bladder contains stones, and the patient cannot count on being exempt from repetitions of the paroxysms produced by their passage. The only effectual mode of preventing the recurrence of the disease is to dilute the feces and strain them through a sieve.

Acute diffuse peritonitis may be accompanied by pain resembling in intensity that of hepatic colic; but in determining the existence of the latter, peritonitis is excluded by the absence of tenderness diffused over the abdomen, of rigidity of the abdominal walls, of tympanitic enlargement, of no acceleration of the pulse and pyrexia, together with the general prostration which belongs to the clinical history of peritoneal inflammation. In the case of intestinal colic the pain is more paroxysmal, with intervals of complete relief. Intussusception and internal strangulation of the intestine are excluded by the absence of a tumor caused by the accumulation of the intestinal contents at the point of obstruction, by the absence of intestinal obstruction and of acceleration of the pulse, together with the greater gravity of the general symptoms in those affections. In acute gastritis vomiting is a prominent symptom than in hepatic colic, and the greater gravity of the affection is shown by the pulse and by the general symptoms. In some cases of hepatic colic the pain extends downward in the direction of the right ureter, so that the passage of a calculus along this duct may be suspected. The absence of certain symptoms belonging to the history of so-called renal colic—namely, retraction of the testicles, deficiency of the urine, hæmaturia, etc.—will serve to exclude this affection. Knowledge of the occurrence of one or more previous attacks which have been ascertained to be due to the passage of gall-stones will aid in determining the diagnosis. The age of the patient is of no account in the diagnosis. Gall-stones may form at any age, but they are most likely to form in middle or advanced life, and in females oftener than in males.

In the great majority of cases gall-stones escaping from the gall-bladder

find their way into the intestine, giving rise to no evil results beyond the pain, etc. which their passage occasions; but occasionally a stone becomes impacted in the biliary canal, and if situated in the common or hepatic duct retention of bile ensues, giving rise to persisting jaundice and structural changes within the liver from the distension of the bile-ducts. Charcot has described paroxysms resembling those of malarial fever, sometimes recurring regularly and presenting the quotidian, tertian, or quartan type of an intermittent, and sometimes recurring without regular periodicity. To these paroxysms this author has applied the name *hepatic intermittent fever*. They differ from intermittent paroxysms due to malaria in the time of their occurrence, this being usually in the afternoon or evening, whereas malarial paroxysms generally occur before midday. They are probably caused by septic infection incident to suppurative inflammation of the duct at the seat of the impaction. The prognosis is unfavorable, death taking place sometimes suddenly in a paroxysm. Recovery may follow the passage of the stone, either through the common duct into the duodenum or by ulcerative perforation into the intestine.¹

Stenosis of the colon or duodenum may result from the projection of the ulcerated opening into those portions of the intestine. Intestinal hemorrhage is an occasional effect of ulcerative perforation, and death may take place from the loss of blood. Permanent obliteration of the canal of the cystic or common duct may result from the inflammation and ulceration caused by the presence of the stone. The formation of a stone within the liver is one of the causes of hepatic abscess.

The rationale of the formation of gall-stones is not well understood. Probably the deposit in a solid form of certain of the constituents of bile takes place in consequence of the presence in the biliary passages or gall-bladder of mucus, collections of which serve as the nuclei for the formation of calculi. Hence gall-stones may be the result of inflammation of the gall-bladder. It has been conjectured that cholesterin may be deposited in consequence of the bile losing the faculty of holding this principle in solution from a diminution of the taurocholic acid. It is not improbable that an excess of the salts of lime or of bile-pigment may lead to the production of calculi. Undue accumulation and retention of bile in the gall-bladder, and an unduly large proportion of solid constituents, may be considered as entering into the causation.

The TREATMENT of a paroxysm of hepatic colic consists of palliative measures. Opiates are called for in doses proportionate to the intensity of the pain, either administered by the mouth or rectum or hypodermically. If the suffering be great, the inhalation of chloroform or ether should be resorted to. Warm anodyne fomentations may be applied to the seat of pain. The hot bath may aid in procuring relief. The local application of cold by means of a bladder filled with pounded ice has been found to be useful as a palliative measure. Remedies to palliate vomiting may be indicated. Effervescing draughts and the hydrocyanic acid may be employed for this purpose. An alkaline remedy may be found useful if, as is frequently the case, the matters vomited show notable acidity of the stomach.

Emetics and cathartics have been advocated under the notion that they aid in the passage of the stone. It is irrational to suppose that they have this effect, and clinical observation does not furnish evidence of their value. The passage of the stone is due to the accumulation of bile behind it after it enters the common duct, and to contraction of the gall-bladder, which contains muscular fibres. These are wanting in the cystic and common ducts. Exciting

¹ Vide cases reported by Prof. William Osler, in *Medical Times and Gazette* (London), July 30, 1881.

the movements of the stomach and intestine by emetics and cathartics, if any effect be exerted, is as likely to retard as to favor the onward passage of the stone. Opium and anæsthetics probably promote its passage. If the distended gall-bladder form a tumor which is appreciable by the touch, an effort may be made, by pressure with the fingers, to propel the bile in the ducts and thus aid in the removal of the obstruction.

It is desirable, if possible, to effect the solution of gall-stones within the gall-bladder. The alkaline carbonates are given for this purpose. A treatment for this end, known in France as Durande's method, consists in the administration of sulphuric ether and the spirits of turpentine (3 parts of the former to 2 parts of the latter). Buckler¹ has proposed the use of chloroform in view of the solvency of cholesterin in this liquid. He has reported a case in which an indurated tumor felt through the walls of the abdomen, directly over the inferior margin of the liver, disappeared in five days under the use of chloroform given in teaspoonful doses after each meal. It was concluded that the tumor was the gall-bladder distended with calculi, but there is room for doubt as to the correctness of this diagnosis. It seems hardly probable that any remedies can be introduced into the system so as to enter into the composition of the bile largely enough to dissolve the cholesterin of which mainly biliary calculi are composed. Bartholow proposes to puncture the gall-bladder with a fine exploring trochar and to inject through the canula a suitable solvent.

The occurrence of gall-stones cannot be anticipated, but, being known, it is of course desirable to prevent the formation of others. It is to be remarked that clinical experience is not to be relied on as affording evidence of prevention, inasmuch as the success of preventive measures cannot be proven. It would seem that sedentary habits predispose to the formation of gall-stones. A change in this respect is therefore advisable. Harley and Bartholow attach much importance to restriction of diet as regards fatty, starchy, and saccharine articles of food. Buckler suggests the hydrated succinate of the peroxide of iron in cases in which gall-stones are known to have been passed, the object being to prevent their further formation, this remedy, as he supposes, controlling the fatty or cholesteric diathesis.² The alkaline mineral waters of Carlsbad, Vichy, and Marienbad are held in much repute as preventing the formation of gall-stones. The soda salts are considered to be most effective by Harley and Bartholow. The sulphate of soda is recommended by Harley, and the phosphate by Bartholow. The latter recommends a drachm of the phosphate of soda three times daily. He attributes the usefulness of this remedy in part to a cholagogue effect. Alonzo Clark considers the bicarbonate of soda an effective remedy, provided it be continued for a sufficiently long period. This remedy can be taken in considerable doses for a very long period without any apparent ill effects. A medical friend of the author has taken from a quarter to half an ounce daily for the last thirty years.

Gall-stones of sufficient size to occasion intestinal obstruction are sometimes lodged in the alimentary canal. These escape from the gall-bladder, not through the biliary passages, but by ulceration, the walls of the gall-bladder becoming adherent to the duodenum or to some other portion of the intestine.

Olive oil, taken largely, is a popular remedy for gall-stones. This remedy sometimes causes the discharge of small, hard bodies supposed to be biliary

¹ *American Journal of the Medical Sciences*, July, 1867, p. 51.

² This remedy is given by Dr. Buckler as follows: Hydrated succinate of the peroxide of iron, $\mathfrak{z}$ iss; water, $\mathfrak{f}\mathfrak{z}$ viiss; a teaspoonful after each meal, continued for several months, and resumed at intervals afterward.

calculi. These are composed of a concrete form of fatty matter, like the bodies passed in some of the cases of fatty diarrhoea which have been reported. A case is quoted by Dunglison in which olive oil, taken abundantly for the relief of pains attributed to gall-stones, caused a discharge of fatty matters of a globular form, varying in size from that of a small pea to that of a grape, and of sufficient consistence to be cut with a knife, like soft wax.¹

[Two surgical operations—cholecystotomy and cholecystectomy—are performed for the relief of intractable cases of hepatic colic. The first consists in removing the calculi from the gall-bladder and returning the latter to the abdominal cavity after suturing the incision made in its wall; while by cholecystectomy is understood the excision of the gall-bladder after ligation of the cystic duct. If a calculus is impacted in the common duct, or if the latter is obliterated by adhesions of its mucous lining, an artificial outlet may be made for the bile by the operation of "cholecystenterostomy," which consists in establishing a communication between the gall-bladder and the small intestine. The reader is referred to works on surgery for statistics and other details of these operations.—H.]

CHAPTER VIII.

SPORADIC CHOLERA.—CHOLERA INFANTUM.—ASIATIC CHOLERA.

Sporadic Cholera: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Cholera Infantum.—Epidemic Cholera: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Prevention; Treatment.

SPORADIC CHOLERA may be considered as a functional affection of the stomach and intestine. Epidemic or Asiatic cholera belongs more properly among infectious diseases; but inasmuch as the symptoms and lesions are in great part referable to the intestine in this affection, it is placed in this chapter for convenience of reference. Moreover, the symptoms in some cases of sporadic cholera simulate closely those of epidemic cholera, and this is a reason for placing the two affections in juxtaposition. Cholera infantum, belonging among the diseases of children, does not come within the scope of this work. I shall, however, notice it briefly, referring the reader for a fuller consideration of it to works devoted to the diseases of children.

Sporadic Cholera.

The affection called cholera in its ordinary form is commonly known as *cholera morbus*. Aside from the incongruity of associating these two words, the one of Greek and the other of Latin derivation, there is no good reason for appending the word morbus, which expresses no more than is implied in the name of any affection—namely, the existence of disease. The etymology of

¹ *Dunglison's Practice of Medicine*, 1842, vol. i. p. 135.

The reader is referred to *A Treatise on Gall-Stones*, by J. L. W. Thudicum, M. D., London, 1863, for a full consideration of their chemistry, pathology, and treatment. Vide also Murchison's *Clinical Lectures on Diseases of the Liver*, etc.

the term cholera is somewhat doubtful, but it is supposed to signify a flow of bile. The term is of ancient date, and was introduced when various liquids were embraced under the name of bile. Not only is the term sanctioned by long usage, but it would be difficult, with our present knowledge, to substitute a better name for the affection under consideration. The term *sporadic* serves to distinguish this from another affection known as cholera which prevails as an epidemic. To distinguish it from the latter, which emanated from India, it is sometimes called by French writers *European*, and by British writers *English cholera*. Writers on this side of the Atlantic might with equal propriety call it American cholera, since it is sufficiently common as an indigenous affection in America. It is called by German writers *cholera nostras*.

CLINICAL HISTORY.—An attack of sporadic cholera is often abrupt, but in some cases it is preceded, for a period usually brief and rarely longer than a few hours, by a sense of weight or uneasiness referred to the epigastrium or extending more or less over the abdomen, with nausea, occasional colic pains, etc. The attack occurs much oftener in the night than in the daytime. It is ushered in by vomiting, which is speedily followed by purging. Vomiting and purging, occurring in quick succession and recurring either simultaneously or in close alternation, constitute the prominent and distinctive symptomatic features of this affection.

The evacuations from the stomach and bowels are generally abundant, and at first consist of the alimentary and fecal contents. Afterward liquid is vomited, sometimes in large quantity, often having the appearance and taste of bile, sometimes acid, and sometimes so acrid as to occasion a scalding sensation in the throat. In like manner, the dejections become liquid and occasion frequently a burning sensation at the anus. The acts of vomiting and purging occur suddenly with but little premonition. They are often violent, the contents of the stomach and bowels being ejected with force. The acts of purging are preceded and accompanied by colic pains, often extremely severe, which are temporarily relieved by a free evacuation. Severe pains like those of spasm or cramp, often attend the acts of vomiting. In the interval between the acts of vomiting the patient usually suffers from dryness of the mouth and fauces with urgent thirst. The abdomen may be at first voluminous, but after repeated acts of vomiting and purging it becomes contracted. Tenderness over the abdomen is either wanting or slight. Spasm of the abdominal muscles sometimes occurs, causing hard bunches or knots, as in some cases of colic. Hiccough is an occasional symptom.

With the foregoing local symptoms are associated anxiety, restlessness, and a sense of exhaustion proportionate to the violence and duration of the attack. The pulse is more or less accelerated, small, and feeble. The skin is cool or even cold, and is frequently bathed in clammy sweat. The voice is feeble, sometimes altered in quality, and occasionally there is aphonia. In some severe cases cramps occur in the feet, the calves of the legs, and in other situations. These add greatly to the suffering of the patient.

The affection runs a rapid course. After continuing for several hours the acts of purging and vomiting become less severe and occur at longer intervals; the pains, etc. progressively diminish, until at length all the symptoms disappear, leaving an amount of fatigue proportionate to the violence and duration of the attack. The patient usually recovers rapidly. It is remarkable that an affection involving so much disorder should leave the affected organs in a condition to resume so speedily the exercise of their functions. This is the rule as regards the progress and termination of the affection, even if its course be not arrested by remedial interference. Exceptionally, the vomiting

and purging continue, the evacuations from the bowels occur involuntarily, the pulse becomes more and more feeble, coldness of the surface is more and more marked, and contraction of the features takes place; in short, the patient falls into a state of collapse, and dies within a few hours from the onset of the attack. This unfavorable course is extremely rare. I cannot recall an example that has fallen under my observation exclusive of cases occurring in infancy.

PATHOLOGICAL CHARACTER.—Sporadic cholera appears to combine morbid conditions belonging to other functional affections of the alimentary canal. In a certain proportion of the cases considered as cases of cholera the symptoms are attributable simply to indigestion. Vomiting and purging denote in these cases the coincidence of acute dyspepsia and crapulous diarrhœa. Such cases are usually comparatively mild, and the vomiting and purging cease as soon as the offending contents of the stomach and bowels are expelled. In other cases something more than indigestion is involved in the pathology. The evacuation of liquid, often in great abundance, shows hypersecretion or morbid transudation into the stomach and intestines. The affection then combines gastrorrhœa and enterorrhœa. In some cases the secretion of bile seems to be increased, but it is difficult to estimate, from the color and the bitter taste of the vomited liquid, the relative proportion of bile. It has been common to suppose that in this, as in various other affections, disorder of the liver is in some way involved. There is no solid foundation for such a supposition; it rests on conjecture alone. It is only in a certain proportion of cases that the bile appears to be secreted in morbid quantity. The limit of our present knowledge of the pathological character of the affection is reached when the different morbid conditions into which it is resolvable are enumerated. These morbid conditions or elements of the affection are indigestion, irritation, spasm of the muscular coat of the stomach and intestines, enteralgia, morbid gastric and intestinal transudation, and perhaps in some cases hypersecretion of bile. By German authors the affection is considered as a variety of gastro-intestinal catarrh. It is impossible to distinguish, by means of post-mortem appearances, sporadic from epidemic cholera.

CAUSATION.—Sporadic cholera is not peculiar to any country, but it is of more frequent occurrence in warm than cold climates. In cold and temperate latitudes it occurs very rarely except during the summer and autumnal months. An elevated temperature is thus involved in its causation, either by contributing to the development of causes or by rendering the system more liable to be affected by them. The affection occurs oftener in childhood, youth, and middle age than in advanced life, and oftener in males than females. Frequently an attack seems to be attributable to the ingestion of particular articles of food or drink. Uncooked vegetables, fruits, ices, etc. are often supposed to stand in a causative relation to it. An attack may follow the arrest of digestion from various causes. In some cases, as already stated, the affection is apparently due to indigestion alone. It is probable that exclusive of these cases the affection involves a special cause, the nature and source of which are unknown. In several cases of sporadic cholera Finkler and Prior have found in the dejecta comma-shaped bacilli which bear some resemblance to the bacilli of Asiatic cholera, but which can be distinguished from the latter by cultivation in different media. Although Finkler and Prior consider their bacilli as the cause of sporadic cholera, other observers have failed to find comma-shaped bacteria in this disease.

DIAGNOSIS.—The diagnostic features of an attack of sporadic cholera are

so strongly marked that little need be said under this head; yet some liability to errors of diagnosis. I have known a case of peritonitis, accompanied by vomiting and purging, to be considered as cholera, the nature of the disease not being discovered until the autopsy was made. It is extremely rare for vomiting and purging to have sufficient force early in peritonitis to lead to this error. The diagnostic mark of peritonitis, however—which will be considered in another chapter—should not be sought after in cases of apparent cholera. The chief liability to error in diagnosis relates to cases of poisoning from the ingestion of acrid or corrosive substances. It is important to discriminate these cases from cholera in view to antidotal treatment, prognosis, and medico-legal considerations. The following are the differential points: The acrid or corrosive poisoning is accompanied by vomiting, which continues for some time before diarrhoea occurs, while in cholera the purging is simultaneous with or follows quickly the vomiting. Moreover, the vomiting in cases of poisoning is out of proportion to the diarrhoea. The symptoms in cases of poisoning denote a condition of great gravity; the pulse is more frequent and smaller, the expression is more anxious, the face more guarded, etc., than in the majority of cases of cholera. Redness or swelling of the mouth and throat distinguishes certain cases of poisoning. There is also marked tenderness over the stomach in cases of poisoning, and more excruciating pain in this situation in the intervals between the attacks of vomiting; in short, the symptoms of gastritis are present. The matter is frequently bloody. Finally, in cases of poisoning the symptoms are usually present soon after a meal or the ingestion of something containing the poison.

During the prevalence of epidemic cholera it is not always easy to distinguish cholera nostras from Asiatic cholera. In doubtful cases the detection of the cholera bacilli of Koch and their cultivation suffice to establish the diagnosis.

PROGNOSIS.—As already stated under the head of the Clinical History, this affection in the vast majority of cases intrinsically tends to a rapid fatal termination is a rare exception to the rule; yet the fact that a small number of cases sometimes fatal is to be borne in mind, and should enforce the adoption of prompt and effective measures of treatment. Occurring in persons already afflicted with some important disease, the prognosis is of course not so favorable when healthy subjects are attacked.

TREATMENT.—In the treatment of sporadic cholera the first object is to ascertain whether the matters vomited have contained ingesta in moderate or great abundance. If not, and if there be reason to suppose that the stomach contains undigested aliment, a mild emetic may be given. Almost invariably, however, the contents of the stomach are expelled with the first attack of vomiting, and as an emetic is indicated for no other object it is very rarely resorted to. In my own experience I have not prescribed an emetic in this disease for the last thirty or more years. The next object is to arrest the vomiting and purging, together with the pain, etc., by the employment of a small dose of opiate in doses sufficient to effect this object. In the vast majority of cases this object may be speedily effected. The form of opiate to be chosen with reference to promptness of action and its retention. For this purpose the black drop, and an aqueous solution of opium are well suited for the management of this affection, but Magendie's solution, or a salt of opium placed dry upon the tongue, is in general the best form. A full quarter or half a grain of a salt of morphia or an equivalent dose of any other preparation to an adult—should be given directly after an attack of vomiting. The first dose will perhaps be immediately rejected; if so,

ould be at once given. If a second and third dose be instantly or quickly ejected, the administration by the mouth should be abandoned, and from one to two drachms of laudanum or an equivalent dose of some other preparation may be given in a little thin starch or mucilage *per enema*. The enema should be given directly after an evacuation, and the patient should be instructed to resist as long as possible the inclination to expel it. If the first enema be quickly rejected, a second and a third may be given. If the attempt to administer the opiate by the mouth and rectum fail, the hypodermic injection may be resorted to. In whatever way the remedy be introduced, it is to be repeated after an interval of from half an hour to an hour until the vomiting and purging are arrested, the effects of each dose being carefully watched and the intervals being sufficiently long to avoid any risk of inducing narcotism.

An important part of the treatment is the withholding of liquids. The intense thirst leads the patient to drink largely between the acts of vomiting, and this tends to prolong the affection. The drink should be restricted to a tablespoonful of ice-water at short intervals, or, what is better, small pieces of ice may be taken frequently and allowed to dissolve in the mouth. Strict compliance with injunctions on the score of drink is essential to the prompt success of the treatment. If there be great prostration a little spirit and water may be taken, if retained, at short intervals.

In my experience this method of treating sporadic cholera has proved uniformly successful, and complete relief may generally be expected within an hour. No apprehension need be entertained with respect to the sudden cessation of the vomiting and purging; and the more quickly the arrest is made the better after a free evacuation of the stomach and bowels. Mercury is, to say the least, superfluous. The success of treatment without it is all that could be desired.

Care as regards diet is alone required in most cases after the affection is arrested.

I do not deem it necessary to consider other methods of treatment, since the success of the plan just stated is, as far as my experience goes, uniform and immediate. The only objection to the plan is that some persons are unpleasantly affected by opium, and after the affection is arrested the effects of the remedy may be more or less annoying for a time. This objection has not much weight, since the after-effects of opiates, however distressing, occasion far less suffering than the continuance of cholera; but they who frequently experience annoyance after the use of opium, under certain circumstances take it without inconvenience, and I have been led to observe that the after-effects are likely to be slight or wanting when opium is given in this affection to patients who usually suffer from these effects.

Cholera Infantum.

The name cholera infantum, or the more popular phrase *summer complaint*, is supposed by some to denote an affection peculiar to this country. The morbid phenomena, however, considered by American writers as belonging to this affection are described in European works under other names. Cruveilhier enumerates many of the symptoms as occurring in cases in which gelatiniform softening of the stomach due to the post-mortem action of the gastric juice is found after death. British writers on diseases of children generally describe the symptomatic phenomena under the head of diarrhoea. Weaning brash, watery gripes, and choleric fever of children are names under which these phenomena were described by Cheyne, Armstrong, and Copland. By some French writers they have been described as belonging

to colo-enteritis, follicular enteritis, choleriform diarrhœa of children, and gastro-intestinal catarrh. German authors consider the affection as gastro-intestinal catarrh.

As commonly used in this country, the term cholera infantum, or summer complaint, embraces different pathological conditions—in fact, distinct affections occurring in children under two years of age. These different conditions, however, may be developed at different periods in the same case. In certain cases the symptoms closely resemble those of the sporadic cholera of adults. A child is seized with vomiting and purging, the latter usually occurring first; the acts of vomiting and purging are violent and frequently repeated; after the contents of the stomach and bowels are expelled the evacuations consist of secreted or transuded liquid in more or less abundance. The attack may cease or be arrested and recovery speedily ensue, as in cases of the sporadic cholera of adults; but this favorable course does not obtain so generally in children as in adults. If the course be unfavorable the vomiting and purging continue; the child is tormented with thirst, but everything is rejected from the stomach; great prostration ensues; collapse follows, and death takes place in one, two, or three days. The fatal result may be preceded by convulsions and coma. In some cases the violent symptoms of cholera cease, and the attack eventuates in a chronic affection accompanied by diarrhœa and occasional vomiting.

In other cases the affection is gastro-intestinal indigestion. These are characterized by diarrhœa, the dejections being lienteric and watery. Vomiting occurs either occasionally and is an accidental symptom, or it may not occur. The diarrhœa is more or less persisting, the discharges being often green in color—an appearance which Golding Bird, and more recently J. Lewis Smith, have shown not to depend on vitiated bile;¹ the appetite is impaired or lost; colic pains are often troublesome; the child progressively wastes, and death may take place from inanition. In another class of cases the affection is either enteritis or entero-colitis. The dejections in these cases contain gelatinous or stringy mucus, and are not infrequently tinged or streaked with blood. Febrile movement, with remissions, occurs in these cases. There is more or less abdominal tenderness and pain. Vomiting may be prominent as a symptom or it occurs only occasionally. Progressive emaciation and debility mark the unfavorable progress of this affection. Head symptoms are often developed in its course. The child becomes dull and somnolent and lies with the eyelids partially closed, frequently rolling the head from side to side. Convulsions and coma may occur. After death a examination reveals the evidences of inflammation of the mucous membrane of the small, and perhaps also of the large intestine, the follicles being especially involved. Enteritis or entero-colitis is liable to become developed in the cases which at first appear to be cases of diarrhœa dependent merely on indigestion. In still another class of cases the symptoms and the appearance after death denote the existence and limitation of inflammation to the large intestine.

Under the name of cholera infantum, then, are commonly embraced cases of sporadic cholera, diarrhœa from indigestion, enteritis, colo-enteritis, and dysentery. The head symptoms which are likely to be developed in unfavorable cases of each of these affections in the young child were formerly incorrectly attributed to inflammation of the meninges of the brain. They constitute the hydrocephaloid affection of Marshall Hall.

The affections embraced under the name of cholera infantum are not, as already stated, peculiar to America, but they doubtless prevail to a much greater extent in certain parts of this country than in Europe, owing, prob-

¹ Vide Smith on Diseases of Children.

ably, in a great measure, to the greater heat in the summer months. The causation has relation to a high temperature, the affections prevailing almost exclusively during the months of June, July, August, and September. Something more than temperature, however, is concerned in their production, for they are almost limited to cities and large towns, and are more prevalent in the Northern and Middle than in the Southern States. Children of the poorer classes, in insalubrious situations and living in crowded dwellings, are more liable to be affected, but the children of those in easy circumstances and of the wealthy by no means escape. The irritation of dentition and the change of diet after weaning doubtless render the system more vulnerable. Infants brought up by hand are especially subject to these affections. The diet of the child after weaning has much to do, if not with the causation of these affections, at least with the ability of the system to resist and overcome them. Restriction to insufficient articles of nourishment, such as arrowroot and gelatin, is one source of innutrition in infancy; but there is reason to believe that infant mortality in cities is attributable in no small measure to the use of diluted, sophisticated, and artificial milk. The importance of undiluted milk from a pure source to the welfare of children is far from being generally appreciated. The quality of milk is of comparatively little consequence after childhood, because it then usually enters but little into the diet, but as the chief reliance is upon milk in infancy its purity is then of the utmost importance.

[Using the term "cholera infantum" to denote an acute enterocolitis of infants, we find that children under six months of age enjoy a comparative immunity from it. According to statistics of Emmett Holt, based on 431 cases, only 12.8 per cent. of the patients were under six months of age, while 59.5 per cent. were between six months and two years old. These great differences as to susceptibility are explained by the fact that after six months of age comparatively few children are exclusively fed with breast-milk. "Nursing by hand" is practically synonymous with improper feeding in the great majority of cases.—H.]

The general principles which should govern the management of the same affections after the period of early childhood are applicable to the different forms of disease embraced under the name of cholera infantum, with certain modifications which will be here referred to very briefly. The treatment, in the first place, has reference to the form of cholera infantum which is presented. In the acute form, resembling the cholera of adults, in which there is a liability to a rapidly fatal termination by exhaustion from loss of fluids, the patient falling into a state of collapse, the indications are to arrest the vomiting and purging, to restore warmth to the surface by the application of dry heat, mustard-water, and the warm bath, and to sustain the powers of the system by stimulants and nourishment. For the arrest of the vomiting and purging opiates are to be relied upon, as in the cholera of adults, but they are to be given with much circumspection in order to avoid risk of narcotism. Exclusive of this form, the affections do not occur with a sudden and violent attack, but as a rule they are developed gradually and tend to become chronic. Measures for the relief of vomiting are—a sinapism to the epigastrium; creosote, which in doses of a sixth or an eighth of a drop in mucilage, repeated after each act of vomiting, sometimes acts like a charm; the subcarbonate of bismuth in doses of from ten to thirty grains; small doses of calomel with chalk, chloroform, and hydrocyanic acid. With reference to this symptom a careful regulation of the ingesta is requisite, and milk with lime-water, given in small quantity at a time, will often be retained when other articles of nutriment are rejected.

With reference to the diarrhœa, occasionally a laxative is useful, and a

few grains of calomel or blue mass, followed by the syrup of rhubarb, are well adapted for this purpose. There are no indications for mercury except as a remedy for vomiting and an occasional laxative remedy, the convenience of its administration being perhaps its chief recommendation in cases of young children. Opium in some form with due circumspection is to be employed. It is most efficient when given by enema, provided it be administered with proper care and retained. If given by the mouth, the Dover's powder is an eligible preparation. Hypodermic injections of morphia should not be given. If the dejections denote acidity, chalk in powder or mixture, or lime-water, is indicated. The mineral and vegetable astringents are highly important. Of the mineral astringents, the most efficient are bismuth, lead, and the persulphate or pernitrate of iron. The nitrate of silver is highly recommended by some authors. Of the vegetable astringents, krameria, tannic acid, kino, catechu, hæmatoxylon, geranium, and rubus villosus are articles from which a selection may be made or which may be tried in succession. Dr. W. Byford Ryan claims remarkably good results from belladonna conjoined with nux vomica and arsenic.¹ [Among the most efficacious drugs are intestinal antiseptics, such as naphthalin, salicylate of bismuth, and salicylate of sodium. It is probably through their antiseptic properties that calomel and creosote are so efficacious. Emmett Holt claims excellent results from salicylate of sodium in doses of from 1 to 3 grains every two hours, according to the age, from three months to three years. "In these doses the aqueous solution is tasteless, and can be readily given in the food or drink."—H.]

Attention to diet and regimen is of prime importance. Many children, there is reason to believe, die with these affections from an insufficiency of nutriment. Pure milk is the most appropriate article of food. It may be rendered more nutritious by the addition of boiled flour, powdered biscuit, or other farinaceous preparations. Gelatin and arrowroot or other amylaceous substances alone are inadequately nutritious. The essence of meat and strong broths are often taken with avidity by very young children, and the desire for them should be indulged and encouraged. This remark is also applicable to broiled tender meats taken in a solid form. Within the past few years the use of raw meat has been recommended as a form of diet adapted to the affections under consideration, and it is frequently taken with relish. Tender beef is to be preferred, but mutton and chicken are sometimes more acceptable to the patient. The meat is to be finely hashed, and may be given in this way, or it may be made into a kind of *purée* by being reduced to a pulp in a mortar and pressed through a fine sieve, so as to separate the vessels and areolar tissue. If the child manifest an aversion to it as thus prepared, the hashed meat or pulp may be rendered palatable by the addition of salt, sugar, or some kind of preserve, or it may be added to a broth made with sago or tapioca. Cooked tender meats, however, are generally more acceptable, equally digestible, and not less nutritious. The liability to tania as a result of eating uncooked meat renders its use of doubtful propriety.

As regards the administration of different kinds of food, the quantity given at a time is to be graduated by the ability of the stomach to retain and digest it; and this is the only rule of limitation. It is of vast importance for the physician not to deem it too trivial to enter into full and minute directions with respect to the details of nourishment. He should bear in mind that children often die from innutrition through the apprehensions and ignorance of nurses and mothers.

[When a hand-fed child under two years of age is attacked with cholera infantum, it is frequently best to suspend the use of milk and farinaceous

¹ *American Practitioner*, June, 1885.

preparations and resort to chicken- and mutton-broth, the juice of "rare" beef, wine-whey, and raw scraped beef. Or, if the feeding has been carried on with milk in a haphazard manner, the following mixture, recommended by Dr. Arthur V. Meigs of Philadelphia, should be given a thorough trial:

"One quart of good ordinary milk is placed in a high pitcher or other vessel and allowed to stand in a cool place for three hours; then one pint is slowly poured off from this, care being taken that the vessel is not agitated, the object being to obtain the upper layer of fluid, rich in fat, and leave the lower, comparatively poor, portion behind. When the child is to be fed there are taken of this weak cream 3 tablespoonfuls, of lime-water 2 tablespoonfuls, and of sugar-water 3 tablespoonfuls. The sugar-water is to be made in the proportion of 18 drachms of milk-sugar to 1 pint of water. This makes only four ounces of food, and if the infant is old enough to require eight ounces at once, double the quantities of each of the ingredients must be mixed. This is simply warmed in a bottle as usual, and is then ready for use."¹

The composition of Meigs's mixture is practically identical with that of human milk when the secretion of the breasts is fully established.

At a foundling institution of Philadelphia called the "Sheltering Arms," in which this food was introduced by Dr. Meigs, the mortality, which had before amounted to about one hundred per cent., has been very materially diminished.—H.]

In conjunction with diet, alcoholic stimulants are highly useful. A few drops of brandy or some kind of spirit may be given at short intervals with advantage. The preparation known as calisaya cordial or elixir is well suited to children, combining a tonic and stimulant in a form agreeable to the taste. The need of a stimulant is shown frequently by the avidity with which children take it in these affections.

Finally, removal from the city, either to a situation on the seaboard or to a salubrious point inland, is the most efficient of all curative means. This measure, if not deferred too long, rarely fails. If other measures be not speedily successful, this, whenever practicable, should be resorted to without delay. If it be not practicable, the child should be in the open air as much as possible, and should be carried daily as far from home as convenient, in order in this way to secure a change of air.

The head symptoms referred to in the clinical history claim sustaining measures, stimulants, and nourishment, conjoined with mild revulsives.

In these affections hope of recovery need not be relinquished under an assemblage of symptoms which may seem to render the prognosis as unfavorable as possible. Patients sometimes recover after lingering for a long time on the verge of the grave. The reason is that the affections, when they prove fatal, do not necessarily involve incurable lesions of structure, but a fatal result is due to protracted irritation, exhaustion, and innutrition.

Epidemic Cholera.

The term epidemic cholera is selected as the one most frequently used and the most convenient to designate a disease which has received a great variety of names, such as Indian, Oriental, and Asiatic cholera, cholera asphyxia, spasmodic cholera, malignant, pestilential cholera, etc. etc. The etymology of the word cholera, it is true, is singularly inappropriate, accepting the derivation which signifies a flow of bile; but our present knowledge does not warrant a name expressive of the pathological character of the disease. Moreover, it is to be presumed that the disease is not essentially the same as sporadic cholera. The two are not merely different varieties of one disease,

¹ *Archives of Pediatrics*, Dec., 1889.

but they are distinct individual affections, having certain prominent symptoms in common, but differing in essential points relating to clinical history, pathological character, causation, and prognosis.

For an account of the prevalence of this remarkable epidemic in different countries and at different times the reader is referred to other works. Suffice it to say that the disease appears to be indigenous in India, and to have existed there, both as a sporadic and an epidemic affection, for a long period. In other parts of the world it has made brief visitations solely as an epidemic. In 1817 it began its march from Bengal, and during the following fifteen years it traversed nearly the whole of the known world. It prevailed in different parts of the American continent for the first time in 1832, and again in 1834. It began its march a second time from India in 1847, and again traversed the greater portion of the globe, prevailing in the United States in 1849, '50, '51, and '52. Beginning again its march over the globe in 1864, it reached this country in 1866, and during this and the following year it prevailed in many of the large towns in the different States of the Union. It may be proper to add that my opportunities for observing the disease in 1849 and 1852 were ample. During these years I treated, in hospitals and in private practice, about 200 cases, recording at the bedside the histories in about 90 cases. A few cases came under my observation in 1866 and 1867. The disease prevailed in different parts of this country in 1873.¹ In 1883 cholera appeared in Egypt, and since then it has prevailed in Italy, Spain, and the southern part of France. [In the month of September, 1887, a steamer from Marseilles, the "Alesia," entered New York harbor with eight cases of cholera on board, and about twenty-six more cases developed among the immigrants while they were in quarantine. In the same year, in October, other cases were brought to the port of New York by a French steamer. In 1892 the harbor of the same city was again invaded by cholera, and the greatest apprehension that the disease might gain a foothold in the country during the approaching summer was excited. By the strictest observance of quarantine regulations both in 1887 and subsequently the dreaded pest was excluded.—H.]

ANATOMICAL CHARACTERS.—With the exception of the presence in the intestines of specific organisms, there is nothing in the pathological anatomy of Asiatic cholera which, so far as at present known, can be considered as pathognomonic of the disease. The same changes may be met with in severe cases of sporadic cholera. The anatomical appearances vary according as death takes place during the algid stage or during the stage of reaction. The changes of the algid or asphyctic stage will be first described. Post-mortem rigidity is marked; it comes on soon after death and continues for a long time. In some cases shortly after death visible twitchings of the muscles occur, and occasionally considerable movements of the limbs. The heat of the body is preserved for a long period after death, and there may be even a post-mortem elevation of the temperature. The surface of the body has cyanotic hue, especially in the dependent parts and in the extremities. The serous surface of the small intestine has a rosy color. The intestine is not distended with gas, but in typical cases it contains a large (sometimes an enormous) quantity of yellowish-white fluid, holding in suspension small white flakes, and hence presents a heavy, flabby, sodden appearance. The mucous surface of the small intestine is swollen, œdematous, moderately congested and may contain ecchymoses. The congestion and the extravasations are more

¹ For an account of the cholera epidemic in 1873, vide *Reports prepared under Direction of the Surgeon-General of the Army, 1875*, published by the Government of the United States.

marked in the lower part of the ileum, and usually are not present in either the large intestine or the stomach. The solitary follicles and Peyer's patches are, as a rule, considerably swollen, and are frequently surrounded by a zone of congestion. The mesenteric glands are moderately enlarged. The surface of the mucous membrane is coated with tenacious mucus. There are marked inflammatory changes in the intestinal coats, indicated by an increased number of lymphoid cells in the mucous and submucous coats. After death the epithelial cells lining the mucous membrane are extensively desquamated, and may be found in the intestinal contents. The view has prevailed that this desquamation occurs during life and constitutes a lesion characteristic of cholera. Competent observers have failed to find intestinal epithelium in any considerable quantity in the discharges during life. There is no ground for assuming that during life an extensive desquamation of the epithelium takes place.

In the intestinal contents and in the walls of the intestine are found comma-shaped bacilli, which were discovered by Koch, and which will be considered fully under the head of Causation. The comma bacilli are usually abundant in the intestinal contents. They are found in the glands of Lieberkühn, between the epithelium of these glands and the membrana propria, and to some extent in the tissue outside of the glands. They are not present in the blood or in other organs of the body.

Changes in other parts of the body are in great part explicable by the enormous transudation of fluid from the blood into the intestines. The blood is dark, and from loss of water is so thick and viscid that it circulates with difficulty during life. It is accumulated chiefly in the large veins and in the right cavities of the heart, where it may be fluid, or it may contain soft, dark, or in some cases decolorized clots. The heart, especially its left ventricle, is generally firmly contracted. By way of compensation for its loss of serum, the blood absorbs fluid from the tissues, and hence these are found abnormally dry. The muscles are firm, dry, and dark-red in color. In consequence of the concentration of the fluid in the serous cavities, the pleura, pericardium, and peritoneum are often covered with a thin layer of sticky substance which has been sometimes mistaken for an inflammatory exudation. The meningeal vessels of the brain and cord are often congested. The cerebro-spinal fluid is diminished, and the substance of the brain and cord is firm and dry. The lungs collapse to an unusual degree in consequence of the empty and dry state of the bronchi. The upper portion of the lungs is usually dry and light colored, and the lower portion is frequently engorged with blood. There are sometimes hemorrhages in the lungs. Small ecchymoses are usually present in the tissue of the pleural and of the pericardial membranes. The spleen may be small, fatty, and dark red, or it may be swollen. There is nothing noticeable in the liver. The kidneys in this stage are not usually swollen. The veins may be somewhat distended, and ecchymoses are often found. Yellowish-white patches in the cortex of the kidney, indicating fatty degeneration of the epithelium, appear in the asphyctic stage, but they are more abundant later. The mucous membrane of the pelvis and calyces is hyperæmic and ecchymosed. The bladder is contracted and nearly or quite empty.

The composition of the blood in cholera patients has been studied with great care by C. Schmidt. He found that the degree of concentration of the blood generally reached its maximum in thirty-six hours after the onset of the choleraic discharges, at which time the relative proportion of solid constituents may be nearly one and a half times greater than normal. This increase pertains mainly to the organic matters in the blood. As it is chiefly the chloride of sodium that escapes in the transudation, the relative quantity

of phosphates and of potash salts in the blood is increased. The function of the kidneys being suspended, there is an accumulation of urea and extractive matters in the blood. The percentage of red and white corpuscles in a given quantity of blood is increased. The red corpuscles are shrunk. The white corpuscles are often found in clumps in the blood after death.

In the stage of reaction, or typhoid stage, the morbid changes are notably different. The tissues no longer are abnormally dry. The intestinal contents do not present the rice-water character, but are stained with bile and sometimes with blood. They usually have a pasty consistence. The solitary follicles and Peyer's patches may be pigmented. The congestion may have disappeared, or in its place there may have developed a more intense inflammation than was present in the first stage. Follicular ulcers are not infrequently seen. Changes similar to those in dysentery, with diphtheritic inflammation and necrosis, occasionally make their appearance in this stage in the large intestine. In the brain and cord there are often congestion and increase of the cerebro-spinal fluid. The lungs not infrequently are oedematous and hyperæmic. Pneumonia may develop in this stage. The spleen may be normal in size or swollen. The most important changes relate to the kidneys. Following the anæmia of the first stage, parenchymatous and fatty degenerations of the renal epithelium ensue. Sometimes an acute diffuse nephritis develops. The kidneys are congested and swollen, especially in the cortical portion. Yellowish streaks, indicating fatty degeneration, appear in the swollen cortex, in which the normal markings are obscured. The dark-red color of the pyramids contrasts with the yellowish-white aspect of the cortex. The epithelium of the tubes in many places is desquamated and has undergone parenchymatous and fatty degeneration. Hyaline, granular, and fatty casts are found in the tubes. Parenchymatous degeneration of the liver and of other organs may be present in this stage.

CLINICAL HISTORY.—In the great majority of cases the disease is preceded by simple diarrhœa, the dejections being greater or less in number, copious, and painless. The duration of this preliminary diarrhœa varies in different cases from a few hours to several days. With this diarrhœa in some cases occasional vomiting occurs. Aside from these symptoms, nothing denotes a tendency to the disease. The system otherwise is but little or not at all disturbed, and it is often difficult to persuade the patient that the intestinal disorder is of any special importance. Of 45 cases in which the existence or otherwise of premonitory diarrhœa was noted in the histories which I have recorded, it existed in 34 cases and was wanting in 11.¹ Statistics on a larger scale show a much smaller proportion of cases in which the premonitory diarrhœa is wanting. Thus the report of the General Board of Health of London for 1848–49 contains the statement by Dr. MacLoughlin, one of the sanitary inspectors, that of 3902 cases the premonitory diarrhœa was not wanting in a single case. Of 142 cases treated in hospital in Paris by Michel Levy, the premonitory diarrhœa was wanting in only 6. Of 274 cholera cases treated in the different Parisian hospitals in 1853, the existence of premonitory diarrhœa was ascertained in 140, in the remainder of the cases it being absent or its existence not ascertained. By some the period during which the premonitory diarrhœa exists is reckoned as a stage of the disease. This is obviously improper, as there is nothing then distinctive of epidemic cholera, and during the prevalence of the epidemic very many have the same kind of diarrhœa without the development of cholera. The simple diarrhœa which

¹ In connection with the history of a cholera epidemic in Buffalo in 1849, by the author, was published a tabular abstract of the histories of 33 not fatal and of 34 fatal cases. (*Vide Buffalo Medical Journal*, 1850, vol. v.)

prevails extensively during the prevalence of cholera is called, in France, *cholerine*—a term adopted to a considerable extent in other countries. By German writers, however, this term is used to designate a mild form of cholera. In a practical view, the importance of taking cognizance of the premonitory diarrhoea is very great, as will presently appear.

The development of cholera is generally first denoted by characters relating to the intestinal evacuations. If diarrhoea have existed, the discharges are suddenly increased in quantity, or sudden and copious liquid discharges without previous diarrhoea mark the onset of the disease. This constitutes the attack, and in the majority of cases it occurs during the night. The characteristic stools consist of a thin liquid generally known as the rice-water or choleraic discharge. The liquid is generally yellowish-white and slightly opalescent. It contains in greater or less abundance small, white, solid particles, like grains of rice in rice-water or flakes of curd in whey. It is devoid of bile, but may be somewhat blood-stained. There is no distinctive odor. The reaction of the fluid is neutral or slightly alkaline. It contains a remarkably small quantity of solid constituents. These do not usually exceed 1 to 2 per cent. The specific gravity varies between 1006 and 1013. The chief solid ingredient is chloride of sodium. There is also present some carbonate of ammonium, which gives the alkaline reaction, and a very small quantity of albumen. The particles resembling rice-grains are composed of mucus with granular matter and some pus-cells. Occasionally a few cylindrical epithelial cells may be found, but they are not abundant. Various low vegetable organisms are present in large number. Of these the only ones of importance are the comma bacilli already mentioned, which, as will be shown under the head of Causation, are doubtless the specific cause of the disease. The quantity expelled at each act or in the aggregate is very variable. A large quantity, enough to nearly fill an ordinary chamber-pot, sometimes escapes at a single defecation, or the quantity with each act may be small. The quantity is not always in proportion to other symptoms denoting gravity. The defecations are not accompanied by pain, but by a sensation of relief. There is no smarting at the anus. The patient is suddenly impelled by a sense of distension to evacuate the bowels, and when the quantity is large it escapes very rapidly. In some cases the evacuations, after several have occurred, cease; and in other cases after a time the liquid flows away constantly, the patient being unable to prevent it. The characteristic defecations are sometimes wanting. The disease has been called *cholera sicca* when death takes place without choleraic discharges. The name, however, is inappropriate. In the so-called cholera sicca the rice-water-like liquid is present in the alimentary canal, and the quantity found after death may be unusually large. It is conjectured that in these cases the peristaltic movements of the intestine are paralyzed, so that the intestinal contents are not expelled. These cases terminate fatally with great rapidity.

Vomiting usually occurs. In a diagnostic and pathological view it is less important as a symptom than the characteristic diarrhoeal discharges. In some cases it is a prominent and persistent symptom, everything taken into the stomach being rejected; but in other cases it occurs occasionally, and sometimes it occurs at the onset and ceases. The matter vomited is a watery liquid, frequently consisting chiefly of water which has been drunk, but sometimes it is evidently a transuded liquid. The quantity may exceed that of the liquids ingested. The vomited liquid is usually neutral, but it is sometimes acid. The vomiting is not preceded or accompanied by much nausea. The act of vomiting occurs suddenly, and appears to arise simply from distension of the stomach.

These symptoms, conjoined with a sense of prostration, more or less feeble-

ness, and generally frequency of the pulse, coolness of the skin, or perspiration, with, in some cases, cramps of the muscles of the limbs, may constitute the clinical history of the disease. In other words, the disease may either end spontaneously or be arrested without symptoms other than those just described. The vomiting and purging cease, improvement as regards the other symptoms follows, convalescence is at once declared, and recovery is rapid. The duration of the disease in these cases is brief—a few hours only. In a large proportion of cases, however, the disease does not pursue such a favorable course. A group of striking symptoms becomes developed, and the disease passes into what has been called the algid or cyanosed stage, or more commonly the stage of collapse. It remains to sketch the further clinical history in these cases.

Important symptoms pertain to the circulation. The pulse is usually frequent and proportionately feeble, beating 120, 130, or 140 per minute, but in some cases it becomes more and more feeble without acceleration. I have observed it to fall below the normal frequency. When the state of collapse is fully developed the pulse at the wrist is extinct. Feebleness or absence of the apex-beat of the heart and of the heart-sounds also shows greatly diminished power of this organ. The blood stagnates in the veins, giving rise to lividity at the roots of the nails and a dusky hue of the prolabia, face, and surface of the body generally. Hence the significance of *cholera cyanosis* and *cholera asphyxia* as names of this stage of the disease. If venesection be practised, the blood trickles from the aperture, not flowing in a projected or continuous stream. Leech-bites do not bleed as usual. The blood is manifestly thicker than in health.

The respiratory system presents striking symptoms. The number of respirations is usually increased, but is sometimes diminished. Dyspnea is occasionally complained of, and sometimes exists in a distressing degree, owing to the feeble circulation, from the thickened state of the blood. The respiration is frequently suspirious or sighing, and irregular in rhythm. The expired air, when the collapse is complete, is low in temperature as compared with health (76° or 80° F.), giving to the hand a sensation of coolness. It contains more oxygen and less carbonic acid than in health, showing a notable deficiency of the changes incident to the function of respiration. The voice undergoes a marked change, becoming feeble, raised in pitch, husky, and not infrequently extinct, attributable in part to muscular debility, but chiefly to dryness and stiffness of the vocal cords. In the moribund state the tracheal râles which so often precede death from other diseases are wanting.

Very little pain is experienced except from muscular contractions or cramps. As regards the nervous system, the disease is characterized by mental indifference or apathy. The patient has no apprehensions, although prior to the attack there may have been intense dread of the disease. In some cases there is great restlessness and jactitation, and in other cases the patient lies quietly, save when disturbed by evacuations and cramps. The latter give rise to most of the suffering. Cramps are usually but not invariably present. They are seated especially in the feet, calves, and abdominal walls, the muscles of the upper extremities and even of the face being somewhat affected. The prominence of this symptom renders the name *spasmodic cholera* significant. The muscular strength in some cases is retained in an extraordinary degree. Patients if not prevented will sometimes get up and walk about even a few moments before death.

The functions of most of the secretory organs are nearly or quite suspended. No bile is contained in the matter vomited or in the dejections, and the urine is suppressed. Patients do not weep. It is a remarkable fact, however, that in nursing women the lacteal secretion may continue. The disease also does

not prevent the occurrence of menstruation, but the menstrual discharge is diminished. The skin, in addition to its cyanosed appearance, is cold and often covered with a copious, viscid perspiration; but in other cases it is cold and dry. The coldness of the surface is like that of a cadaver. Of this, however, the patient is not conscious; on the contrary, there is generally a sense of heat and a desire to be uncovered. The heat of the body is diminished, as shown by the thermometer in the rectum or vagina. The axilla in this disease does not give a fair representation of the internal temperature. The diminution ranges generally from two to four degrees below 98°, but it may fall to 90°, and even considerably lower, and it has been known to fall to 73°. The skin is frequently shrivelled and wrinkled like the arms of washerwomen. Its elasticity is diminished, as shown by its subsiding very slowly after being pinched up. The tongue gives to the touch a sensation of coldness. Thirst is a prominent symptom. The patient craves constantly cold drinks, and iced water or ice is taken with great avidity.

The general aspect in the collapsed state is highly characteristic. The features are contracted, the eyes sunken; the whole body is diminished in bulk; the patient appears to have suddenly grown old, and the countenance is often so much changed that the person is scarcely recognizable by familiar friends.

Of the foregoing symptoms, most are present in all cases in which the disease is not speedily arrested. Differences relate chiefly to the degree of severity of the disease. In stating the condition of patients it is customary to say *before* or *after* collapse, and to express different degrees of the collapsed state by saying *semi-collapsed* or *completely collapsed*. Collapse is complete when the pulse at the wrist is extinct, the surface cold, etc. The collapse may ensue with more or less rapidity—from an hour to six or eight hours after choleraic dejections occur. It occurs almost invariably in fatal cases, the mode of dying being of course by asthenia; but I have known cases to end fatally without the stage of collapse, the patient becoming comatose and dying by apnœa.

The patient after emerging from the state of collapse does not, in general, pass at once into convalescence, but there follows a period of the disease commonly called the *stage of reaction*. In this stage there is usually fever, the temperature rising more or less above the maximum of health. Diarrhœa not infrequently continues, the dejections becoming green and gelatinous. Dysentery is sometimes a sequel. In some cases constipation more or less obstinate follows. Vomiting in some cases is a troublesome symptom in this stage, the vomited matter being either green or yellow. Capillary congestion of the surface, especially of the face, is frequently marked, as in cases of typhus. The renal secretion returns, and the urine is albuminous, brownish-red in color, and it contains epithelial, fatty, and hyaline casts, together with degenerated renal cells, and usually also red and white blood-corpuscles. This stage is not devoid of considerable danger. The patient may be worn out with continued vomiting or diarrhœa; somnolency and coma become developed in a certain proportion of cases, dependent probably on uræmia; and delirium of a passive kind is not uncommon, together with subsultus, sordes, and other symptoms of the typhoid state. Pneumonia is sometimes developed. A fatal termination occurs in a pretty large proportion of the cases in which the stage of reaction takes place; and in the cases which recover the powers of the system are generally impaired for a long period. Exceptionally, patients emerge from the collapsed state and pass either gradually or quickly into convalescence without febrile movement or other symptoms belonging to the stage of reaction.

Epidemic cholera has a brief duration. After the occurrence of the cha-

racteristic choleraic dejections death sometimes takes place within two or three hours, the patient dying as if from profuse hemorrhage. The duration rarely extends beyond ten or twelve hours. If life continue longer and either death or recovery ensue, the disease has run its course, and the symptoms denote its sequels or effects. Assuming the disease to be parasitic, the local conditions for the multiplication of the parasites continue only for the limited period of the duration of the disease proper.

PATHOLOGICAL CHARACTER.—Most of the striking phenomena of the disease are plainly attributable to the blood-lesions resulting from the loss of the constituents found in the choleraic dejections. The blood circulates with difficulty, and the changes incident to respiration take place imperfectly; hence the feebleness and extinction of the pulse, the cyanosis, loss of temperature, thirst, mental apathy, spasm, unchanged expired air, defective secretion, etc. etc. The retention of excrementitious principles in the blood doubtless plays an important part in the production of morbid phenomena. The coma which occurs in some cases may be due to uræmia. Cholesteræmia may occur, since the function of the liver is suspended.

The transudation, however, which is first in the catenation of appreciable events involves an underlying pathological condition. That this condition is due to the invasion and growth of the cholera bacilli to be presently described is very probable. Koch is of the opinion that these bacilli produce some poison which is absorbed into the system and causes the severe constitutional symptoms and the lesions of organs other than the intestine.

CAUSATION.—Since the preceding edition of this work an important addition to our knowledge of epidemic cholera has been made by the discovery by Robert Koch of a form of bacterium peculiar to this disease and to be regarded as its specific cause. Koch was sent by the German government as the head of a commission to investigate epidemic cholera in Egypt, and subsequently in the East Indies. He discovered the cholera bacillus in Egypt in 1883, and in the latter part of that year and in the early part of 1884 he continued his studies of this organism in India.

The cholera bacillus is shorter, but somewhat thicker, than the tubercle bacillus. It is more or less curved, and from its resemblance in shape to a comma it is called by its discoverer comma bacillus. The curve is not always that of a comma, nor is one end usually thickened, like the upper end of a comma. Sometimes, especially in cultures, the organism presents a spiral or corkscrew shape. These spirals represent either a series of comma bacilli joined together or a spiral growth of a single organism. From this appearance it is claimed that the organism should be called a spirillum or a vibrio, and not a bacillus; but there is some doubt as to the interpretation of the spiral mode of growth. The cholera bacilli multiply by transverse fission.

Although, to a trained bacteriologist, the morphological appearances of the cholera bacillus are quite characteristic, nevertheless, for certainty in diagnosis, it is necessary to resort to artificial cultures of the organism. The cholera bacillus grows readily in a great variety of media, of which the most important are bouillon, nutrient gelatin, agar-agar, blood-serum, potato, and milk. It grows best at a temperature of between 30° and 40° C. (86°–104° F.). It can be cultivated at 17° C. (62½° F.), but its growth nearly ceases below 16° C. The most useful agent for the study of the diagnostic characters of the growth of the cholera bacillus is nutrient gelatin in plate and in test-tube cultures. These characters are manifest within twenty-four hours after inoculating the gelatin and cultivating at a temperature of about 21° C. (70° F.). In the gelatin cultures on plates a typical colony of the cholera

bacillus appears as a small glistening, round particle, which, when examined with a low magnifying power, presents a granular, grayish appearance with well-defined but slightly irregular borders. Each colony is surrounded by a narrow clear ring caused by liquefaction of the gelatin. In test-tube cultures the growth of the colony gradually extends from the surface down and along the line produced by sticking the platinum wire into the gelatin when inoculating the tube. Corresponding to the top of this line, the gelatin appears to be occupied by a round or conical air-bubble, from which the tapering colony extends in the line of inoculation. There is a moderate liquefaction of the gelatin around the colony. Upon sterilized steamed potato at ordinary temperatures the cholera bacillus grows very imperfectly, but between 30° and 40° C. it grows very rapidly. When cultivated and examined in a drop of bouillon the cholera bacilli are found to be endowed with the power of rapid movement.

The form and the development of the cholera bacillus, together with the characters and the conditions of its growth in various culture media, suffice to distinguish this organism from all other forms of bacteria with which we are acquainted. Many other comma-shaped bacteria are known to exist, but all of them, such as the comma bacteria of Finkler and Prior (p. 473), those found sometimes in the saliva, those discovered in cheese, in foul water, etc., can be positively distinguished from the cholera bacilli. The cholera bacilli are peculiar to epidemic cholera, and hitherto they have been found only in the intestines and the dejecta of patients affected with this disease.¹ Moreover, the cholera bacilli are invariably present in the intestinal contents and evacuations of cholera patients, except in a late stage of the disease when the patient is suffering from the sequels rather than from the immediate effects of cholera. It is certain, therefore, that the cholera bacilli and the disease cholera bear a close relation to each other, and it is difficult to conceive that this relation can be any other than that the bacilli are the cause of Asiatic cholera. Inoculation of the cholera bacilli in animals has not given clear and satisfactory results, as animals under normal conditions do not seem to be susceptible to Asiatic cholera. Still, it has been found possible, after neutralizing the acidity of the gastric juice and after paralyzing intestinal peristole by opium, to obtain in animals, by the injection of cultures of cholera bacilli into the stomach, lesions of the intestine similar to those in cholera. The intestines are congested and filled with fluid or semifluid contents, which contain cholera bacilli in enormous numbers. Satisfactory inoculation experiments on animals, welcome as they would be, are hardly necessary to prove the causative agency of the cholera bacilli, as the observations on human beings can hardly admit of any other interpretation than that which has been given. In every case where it has been possible to fulfil all the conditions of a strict proof it has been found that peculiar organisms, whenever constantly associated with the lesions of a given disease, are the specific cause of that disease; and in no instance has support been found for the hypothesis that organisms not found elsewhere and constantly associated with a disease are present simply because the disease makes a favorable soil for their growth. If, then, the cholera bacilli are the specific cause of epidemic cholera, it is important to know all the conditions which are favorable, as well as those which are hostile, to the growth and development of these organisms. Our knowledge of these conditions is as yet imperfect. It has already been mentioned that growth of the cholera bacilli is checked by a temperature much below 16° C. (61° F.). The bacilli, however, are not destroyed by a temperature far

¹ Koch found cholera bacilli in the water of a tank in India which was used for drinking purposes, and which was contaminated with the dejecta and the linen of cholera patients.

below the freezing-point. They do not form spores,¹ and are therefore much less resistant to injurious influences than the spore-forming bacilli, such as those of anthrax. Cholera bacilli in the moist condition, however, may preserve their vitality for five or six months, and after special modes of cultivation for even a year or more. When completely dried the cholera bacilli die within a short time. They are very susceptible to the action of most acids, which even in very dilute solution destroy the bacilli or check their growth. They are destroyed by carbolic acid in one-half of 1 per cent. solution. This agent is recommended by Koch as the most suitable for the disinfection of cholera stools and linen. The cholera bacilli grow rapidly upon linen soiled with cholera dejecta, so that after twenty-four hours this linen seems to present a pure culture of these organisms. After a day or two the bacteria of putrefaction predominate and displace the comma bacilli. The cholera bacilli do not develop in very foul and putrefying substances. The cholera bacilli preserve their vitality for a considerable time in water, but they do not develop in water unless this contain a certain (not too small) proportion of nutritive material.

The question now arises, How far is it possible to reconcile the doctrine of a special contagium in cholera stools and the known facts concerning this contagium with the views derived from a careful study of epidemics of Asiatic cholera? The epidemiological study of cholera has led to a wide although not universal acceptance of the view that Asiatic cholera is not directly contagious. The following are the main considerations upon which is based the opposition to the doctrine of contagion:

1. Of those who are brought into contact with or close proximity to cholera patients the proportion who become affected is not larger than that of those who are not thus exposed. It is a notorious fact that physicians and nurses in attendance upon cholera patients do not contract the disease more frequently than others living in the same locality. In this respect there is a marked contrast between the development of cholera and of typhus fever in hospitals.

2. Although there is no ground for the assumption that an epidemic of cholera can ever originate in a place in which the cholera germs have not been introduced either by persons or by clothing or other substances derived from a cholera locality, nevertheless, imported cases of cholera in situations where the disease had not previously existed very frequently, and perhaps as a rule, do not lead to its diffusion.

3. The epidemic breaks out in a place almost simultaneously in different situations, without any communication of the cases with each other.

4. It is diffused too rapidly to be propagated by contagion. If contagion it must be most highly so to account for the rapidity with which it extends and the latter assumption is not consistent with other facts.

5. There are certain places which possess temporary or permanent immunity against the invasion of Asiatic cholera. Lyons in France is such a place. From its well-known immunity Lyons has become a refuge for persons fleeing from cholera-infected localities. Although such persons are readily admitted into the city, there has never been an epidemic of cholera in this place except in a very limited district. Many places in which there is immunity from cholera are known to exist.

These considerations lead to the conclusion that the spread of cholera is not due to its being directly communicated from those affected with the disease. To explain the epidemiological facts concerning cholera the hypothesis has been

¹ Hüppe and others describe a fragmentation of cholera bacilli into little round bodies, which they claim are more resistant than the bacilli and are capable of developing into bacilli. These round bodies they therefore regard as spores (arthrospores).

advanced, and has met with wide acceptance, that the stools of cholera patients contain a virus which is not capable of producing cholera at once, but must first undergo, outside of the body and probably in the soil, certain unknown modifications or metamorphoses. Cholera has therefore been classified among the miasmatic contagious diseases. The conditions of the soil favorable for the development of epidemic cholera have been investigated most carefully by Pettenkofer. These conditions are—first, a certain degree of porosity of the ground; second, a certain amount of moisture in the superficial layers of the ground, and this amount must be neither too great nor too small, and in most places is indicated by a sinking of the ground-water; and third, a certain amount of organic matter suitable for the growth of the cholera germs in the soil. Such matter is present particularly in soil contaminated by filth or imperfect drainage. It is apparent that these conditions of soil may in certain regions be permanently absent, and in other regions be temporarily absent. Hence is explained the permanent and the temporary immunity of certain places against the invasion of cholera.

The facts which have been mentioned in opposition to the contagion doctrine of cholera and in support of the essential influence of local conditions in the development of the disease have led Pettenkofer and his followers to reject the view that the comma bacilli found in cholera stools are the special cause of the disease. This view, they say, cannot be reconciled with epidemiological facts.

In reply it may be said that the constant presence of cholera bacilli in the intestinal contents of cholera patients is an established fact, and requires an explanation. No satisfactory explanation has been offered or seems possible other than that the bacilli are the cause of the disease. In other words, the dejecta of cholera patients do contain a special poison capable of causing cholera without undergoing any special metamorphosis in the soil. Positive facts speak for the existence of this contagium in the stools, such as the repeated instances in which washerwomen have contracted cholera by washing clothing or bed-linen which has been soiled by the dejecta of cholera patients. Macnamara relates the following well-authenticated case in his own experience in the East Indies:¹ "A small quantity of a fresh rice-water stool passed by a patient suffering from cholera was accidentally mixed with some four or five gallons of water, and the mixture exposed to the rays of the tropical sun for twelve hours. Early the following morning nineteen people each swallowed about an ounce of this contaminated water: they only partook of it once, but within thirty-six hours five of these nineteen persons were seized with cholera. In this instance the choleraic evacuation did not touch the soil; as it was passed, so was it swallowed." Cholera was not prevailing to any considerable extent in the locality at the time. While, then, these and other observations support the view that the cholera stools contain the special agent of infection of the disease, it is to be noted that this infectious agent must be received into the alimentary canal in order to produce cholera. Under ordinary circumstances it is apparent that portions of cholera stools could gain access to the digestive tract only through great carelessness. We know that bacteria are not conveyed into the air from moist surfaces, and, as has already been mentioned, the cholera bacilli are destroyed by being completely dried. The exhalations and the urine of cholera patients do not contain cholera bacilli. These are present only in the discharges from the intestinal canal, and very exceptionally in the vomit. It is explainable, therefore, that with ordinary care those who are in close proximity to cholera patients are not likely to contract the disease merely from such proximity.

¹ Quain's *Dictionary of Medicine*, article "Cholera."

We come, therefore, to the conclusion that an epidemic of Asiatic cholera is due to an infection of the soil or of the drinking-water of the locality by cholera bacilli derived directly or indirectly from the dejecta of cholera patients. That the contamination of the drinking-water with cholera germs may cause an outbreak of epidemic cholera seems certain; but it is not proven that this is a frequent mode of infection. Probably a common source of infection is direct contact with objects which contain cholera bacilli, such as might come from eating uncooked fruit, salads, etc. As to the exact mode of infection we are in most cases ignorant; but from what has been said it is apparent that the known facts concerning the origin and development of epidemics of cholera are not opposed to the acceptance of Koch's discovery of the cholera bacilli and of their causative relation to the disease.

Great importance is to be attached to the auxiliary or predisposing causes of Asiatic cholera, as it is within our power to prevent many of these. Unfavorable hygienic conditions, especially such as affect the purity of the drinking-water and of the soil, are most potent factors in aiding the development of cholera. By improvement in sanitary conditions places have been rendered nearly or quite exempt from the invasion of cholera, even in India, the home of the disease. Individual predisposition also plays an important rôle. The cholera bacilli are destroyed by acids, even by the acid gastric juice. Disorders of digestion, therefore, which reduce the acidity of the gastric juice, facilitate the entrance and development of the cholera bacilli in the intestine. Hence deprivations, intemperance, depressing emotions, over-exertion, fear of the disease, are auxiliary causes in certain cases.

Cholera has prevailed in all climates and at all seasons. In temperate climates it has prevailed most frequently in late summer and in the autumn. Feeble persons are more apt to be attacked than the robust. As regards age, no period of life is exempt, but the largest proportion of fatal cases is among persons advanced in life. Excluding old persons, the mortality is largest after adult age, next in early infancy, and last in childhood and youth. A certain degree of immunity, at least for a few years, is afforded by having experienced an attack of cholera.

DIAGNOSIS.—During the prevalence of cholera there is no difficulty in recognizing the disease when fully developed; that is, when symptoms denoting existing or impending collapse are present. There is scarcely any other disease in which the diagnostic features are so strongly marked; but it is exceedingly important to recognize it before it has advanced sufficiently to manifest its most obvious striking characters. The diagnosis is then to be based mainly on the characteristic intestinal evacuations. As soon as the so-called rice-water or choleraic stools are apparent the patient is to be considered as attacked with cholera. In a very small proportion of cases the evacuations do not occur at all, or not until other symptoms characteristic of the disease become developed. The diagnosis in these cases must be based upon the latter.

It is important to recognize cases of cholera which appear in places where no epidemic prevails. Prophylactic measures to be effectual must be applied to the first cases of cholera which appear in a community. Hitherto it has been by no means easy to distinguish the first cases of cholera, especially when they do not terminate fatally, from sporadic cholera or cholera nostras. We possess, however, in the recognition of Koch's comma bacillus a means of certain diagnosis. In general, from twenty-four to forty-eight hours will suffice to establish the diagnosis. If it happen that the cholera bacilli are found in almost pure cultures upon the surface of the cholera dejecta or upon the linen soiled thereby, the diagnosis is established. Usually it is necessary to

only to make stained microscopical preparations from the stools, but also to prepare cultures; which is done by first making a plate culture in nutrient gelatin. From the characteristic colonies which develop in the gelatin pure cultures may be made in test-tubes containing nutrient gelatin, and specimens can be examined in a drop of bouillon in order to study the properties of the living bacilli. At present, undoubtedly few practising physicians possess the knowledge requisite for the preparation of such cultures. This knowledge, however, is not difficult to acquire, and at least in every large community some one should be found who is capable of making the diagnostic tests which have been mentioned.

Cholera is to be discriminated from the simple diarrhœa which generally precedes it, and which during the continuance of an epidemic affects a large number of persons without eventuating in cholera. It is probable that this premonitory diarrhœa proceeds from the epidemic cause, but cases are not to be considered as cases of cholera when neither the choleraic discharges nor other characteristic symptoms occur. This discrimination is important with reference to determining the rate of mortality and the value of therapeutical measures. The apparent success attending the practice of some physicians or following the employment of certain methods of treatment may depend on cases of simple diarrhœa being reckoned as cases of cholera.

This disease is one of the most insidious in its approaches. Aside from a mild diarrhœa it gives no warning of the attack. So little are patients conscious of danger that they often apologize for giving the physician the trouble of visiting them, when a glance suffices to show that they are on the verge of collapse. It behooves the physician in all cases of simple diarrhœa during an epidemic of cholera to carefully watch the evacuations with reference to the diagnosis. On the other hand, during an epidemic physicians are not infrequently called to see persons who under nervous excitement imagine that they are about to be attacked, when no symptoms of the disease are present. These have been appropriately called cases of *choleraphobia*.

PROGNOSIS.—Of those attacked with cholera, a large proportion die. The average rate of mortality in hospitals varies from one-half to one-third. When developed in hospital wards among patients admitted for other diseases, it proves fatal in the great majority of cases. In private practice, especially among the better classes of society, the mortality is considerably less. In individual cases the prognosis is widely different according to the period of the disease at which the patient is first seen. If the patient be seen immediately after the attack, before serious blood-lesions have occurred, the prospect of an arrest of the disease is good; but if the disease have advanced to the stage of collapse the prognosis is always exceedingly unfavorable. After reaction from the collapsed state the danger is still great, but the cases in which recovery takes place preponderate. The statistical researches of Duchesne show the rate of mortality at different periods of life in the epidemic at Paris in 1849.¹ The proportion in 1000 in subjects less than five years of age was 148; from five to fifteen years, 50; from fifteen to thirty years, 177; from thirty to forty-five years, 254; from forty-five to sixty years, 206; and from sixty to eighty-five years, 162. The mode of dying is in general typical of asthenia. Accumulation of liquid in the air-tubes very rarely takes place.

PREVENTION OF CHOLERA.—The prophylaxis of cholera claims consideration under a distinct heading, and I give it precedence over the therapeutical management, in view of its greater relative importance. In addition to the

¹ Valleix, *op. cit.*

removal, as far as possible, of all the auxiliary causes of disease which contribute to render the special cause of cholera efficient, the prevention involves prompt attention to the diarrhœa which in the great majority of cases precedes the attack. This premonitory diarrhœa is amenable to simple measures of treatment, and if effectually treated there is reason to believe the supervention of cholera is prevented. All physicians who have had much practical acquaintance with this disease will bear testimony—*first*, to the fact that an attack of cholera is generally preceded by diarrhœa; and *second*, to the fact that an attack very rarely occurs when this diarrhœa receives appropriate attention. Giving results of my own experience with respect to the facts just stated, in 1849 for the space of three months I prescribed for as many private patients with the premonitory diarrhœa as my physical endurance would permit, my practice being chiefly among the prudent classes, and I had during that epidemic but 10 cases of cholera in private practice. In only one of these 10 cases did I prescribe for any premonitions, and in the single case the prescription was for a slight nausea only. In each of the 10 cases either the premonitory diarrhœa did not exist or it was neglected. During another epidemic in 1852, I had about the same number of cases of cholera in private practice. In not a single case had I been called upon to prescribe for premonitory diarrhœa, and I prescribed for hundreds of persons with simple diarrhœa, not one of whom had an attack of cholera. The experience of others would doubtless furnish in like manner evidence of the above stated facts, and from these facts the following conclusion may be drawn: Except the very small proportion of cases in which cholera is not preceded by diarrhœa it may with almost absolute certainty be prevented. It needs but a little reflection to see the immense practical importance of this conclusion.

The treatment of diarrhœa during a cholera epidemic is simple. An opiate conjoined with an astringent remedy, regulated diet, rest, and recumbency suffice. A few drops of laudanum with camphor, or the camphorated tincture of opium in conjunction with the tincture of kino, catechu, or krameria, salt of morphia or opium with either tannic acid or the acetate of lead bismuth and capsicum, may be given in doses sufficient to arrest the diarrhœa at once, and repeated often enough to prevent its recurrence. Inasmuch as the bacilli enter the body probably by way of the digestive system the free use of the mineral acids may be useful as a prophylactic measure these being found to be destructive to the parasite out of the body.

The great difficulty as regards the prophylaxis is in the prompt application of simple but effectual treatment in all cases of diarrhœa during the epidemic. Very many pay no attention to the premonitory diarrhœa through ignorance and not a few of those better informed neglect it either from recklessness because they cannot appreciate the fact that a disorder so slight and ordinary can be a precursor of a malady of such gravity as cholera. Public announcements by handbills, articles in newspapers, etc. of the importance of promptly resorting to treatment for diarrhœa fail in accomplishing the object. The only effectual plan is to organize a sanitary police, and to provide for one or two domiciliary visits daily at every house within the limits of the epidemic the purpose of the visits being to inquire if any one be affected with diarrhœa; to impress the importance of immediate attention to it, and when circumstances render it necessary to supply appropriate remedies at once. The plan, faithfully carried out, demonstrates that cholera is in a great measure preventable. The prevention is effected by arresting at once diarrhœa as often and as soon as it occurs. Abundant proof of the successful operation of the system of the house-to-house visitation was furnished by its practical results in London and other towns in Great Britain during the epidemic of 1849.

Another mode of escaping the disease is to remove without the range of its prevalence. Persons not compelled to remain by necessity or by a sense of duty should go beyond the limits of the epidemic; and the removal of persons in districts where, owing to the activity of auxiliary causes, the disease is especially rife, should be enforced as a sanitary measure by municipal authority.

The foregoing remarks relate to the prevention of cases of cholera during an epidemic. To prevent the epidemic is an object of still greater importance. This is to be done by thorough sanitary measures in regard to the removal of filth, attention to sewers, cesspools, and privies, also to wells or other sources of water-supply, together with proper protection against causes of disease from waste-pipes in houses, by providing against overcrowding of tenements, etc., and by efficient quarantine regulations. Ships, merchandise, luggage, etc. coming by sea or land from a cholera region should be effectually disinfected. The clothing of persons from an infected place should be disinfected, but only those need be detained in quarantine who are suffering from cholera or diarrhoea. It is of the utmost importance to disinfect thoroughly the stools, the linen, and the bed-clothing of cholera patients—in fact, everything with which by any chance the discharges of the patient can come in contact. The most useful agent for disinfecting the stools is carbolic acid, which may be employed in a 5 per cent. solution, [or the discharges may be mingled with an equal bulk of a corrosive-sublimate solution, 1:1000. The mixture, after standing for one hour in order to ensure thorough destruction of the disease germs, should be thrown into the sewer. The hands of nurses should be washed in the sublimate solution after coming in contact with the patient, and after each evacuation the patient's fundament should be washed with a solution of corrosive sublimate of the strength of 1:10,000. After each act of vomiting the patient's mouth should be washed with a saturated solution of boracic acid or, as recommended by Shakespeare, with water slightly acidulated with sulphuric acid. No one should be permitted to eat or drink in the sick-room.—H.] Sulphate of iron is not an effective disinfectant for the stools. By these means the introduction, or at least the spread, of cholera germs may be prevented. If these means do not prove protective, it is because they are not, and perhaps cannot be, employed with sufficient completeness; for with our present views of the causation of the disease it may be affirmed that if the cholera bacilli can be completely excluded cases of cholera cannot occur.

When the introduction of the disease is not prevented, the prevention of its diffusion is practicable by the prompt and effective disinfection of every house in which it occurs. In this way an epidemic is "stamped out." That this is practicable was demonstrated in the city of New York in 1866. A thousand cases occurred in that year in different situations widely separated from each other. Cases occurred in 362 houses, all of which were instantly disinfected and all local appreciable causes of disease were removed. In no instance did the disease extend beyond the house in which a case occurred. These facts are of momentous importance.¹

TREATMENT.—To consider the host of remedies and of therapeutical measures which have been advocated as more or less efficacious in the treatment of this disease would require not a little space. There are but few articles in the *materia medica* which have not been tried, even including antimony and drastic purgatives. Much injury has doubtless been done by over-medication under the idea that the treatment, as regards activity, must be proportionate

¹ For further details and for the processes of disinfection, vide *Report of the Metropolitan Board of Health, New York, 1867.*

to the amount of danger from a disease. On the other hand, many remedies which have been employed exert little or no effect either for good or harm. It would be unprofitable to devote space to the consideration of the great variety of practice which the literature of cholera affords. In the parasitic doctrine, a specific remedy must be a parasiticide, causing the parasite to die by its toxic effect upon the parasite its destruction within the intestinal canal. As yet no such remedy is known; but there is reason to think that the disease is frequently controlled by efficient treatment, and that the recovery may depend on the judicious employment of means for that end. In the present state of our knowledge the objects of treatment are the prevention of the immediate serious consequences of the disease, the parasite, and to obviate the tendency to death. I shall limit myself to a brief statement of the principles of treatment which my own experience and reflections have led me to regard as most consistent with our knowledge.

The treatment is to be considered as applicable to the different stages, namely, before collapse, during the collapsed stage, and after reaction. In the first stage the paramount object is the arrest of the intestinal effusion. The first appreciable link in the chain of morbid sequences, if it be promptly arrested before it has proceeded so far as to affect the circulation, the patient is usually safe. The remedy on which the most dependence is to be placed in effecting this object is opium. Some form of opiate is to be given promptly in doses sufficient to effect the object. The form of opiate is to be chosen with reference to promptness of action and probability of its being retained. Opium in substance is unsuitable, for its comparative slowness of its action. Laudanum or the acetated tincture in aqueous preparation is to be preferred; but the article which I have to regard as the most eligible is a salt of morphia, administered by being rubbed dry upon the tongue. In the endeavor to effect the object of treatment in this stage moments are precious, for there is always danger that if the object be not promptly effected the patient will fall into the collapse. The opiate should therefore be given at once in a full dose. A grain of salt of morphia is rarely if ever too large a dose for an adult. A physician should if possible remain with the patient. If the first dose be rejected, a second should be instantly given. The remedy is to be repeated at intervals of from one-half to three-fourths of an hour until the disease ceases. If, owing to the occurrence of vomiting, the administration by the mouth be ineffectual, it should be given by the rectum, and in cases in which the symptoms are urgent both modes of administration should be resorted to. The system, even in this stage of the disease, is not readily affected by the opiate thus given. In view of the importance of the object, if it be necessary to effect it some risk of inducing narcotism is justifiable; but the administration be in the hands of the physician, and the effects of the opiate be watched with care, danger from this source may be avoided. The point is to employ the remedy promptly so as to effect the object, bearing in mind that the delay of half an hour or an hour is often fatal. Relying on the opiate, it is best not to add other remedies, lest by increasing the number of the doses they be rejected. A full dose is preferable to small doses frequently repeated, because the effect within a short space of time is more certain and the remedy is more likely to be retained. Aside from the rejection of the remedy, vomiting is, if possible, to be prevented in view of its prostrating effects. The patient in this stage should be restricted to a very small quantity of water or spirit and water given at short intervals, or in the form of pieces of ice. Perfect quiet is important. He should not be permitted to get up to go to stool, and he should be urged to resist as much as

the desire to evacuate the bowels. Frictions, the warm bath, sinapisms, etc. in this stage are useless and hurtful.

I have repeatedly succeeded in arresting the disease by this plan of treatment, and when it has been arrested before the stage of collapse the recovery is usually speedy. Regulated diet, rest, with perhaps a tonic remedy, suffice for the cure. The bowels should be allowed to remain constipated for several days, and then if movements do not spontaneously occur simple enemas will probably be sufficient. If not, a little rhubarb or some other mild laxative may be given. I believe no other plan of treatment promises more than this, but it is not to be expected that it will always prove successful. It will fail—or rather it is not available—when, owing to the persistent vomiting and frequent purging, the remedy is not retained sufficiently long to exert its effect; and it is not available when, owing to the great rapidity of the transudation, the state of collapse occurs so quickly that there is not time enough to obtain a remedial effect. These difficulties are equally in the way of success from any remedies.

The foregoing remarks on the treatment prior to the phenomena of collapse were written before the hypodermic method of administering opiates and other remedies had come into vogue, and the inquiry has arisen whether by means of this method the opiate plan of treatment of cholera in the first stage may not be carried out more efficiently than by giving opiates by the mouth or rectum. Considering the great importance of the promptness of the effect of opiates, and the uncertainty attending their administration by the mouth or rectum, owing to their rejection by vomiting or purging, and the difficulty of absorption if they be retained in the alimentary canal, the hypodermic method seems to offer a great advantage as regards speediness and reliability of effect. The hypodermic injection of Magendie's solution of morphia was employed in a large proportion of the cases which came under my observation in 1866. The vomiting, purging, and cramps were generally arrested promptly by this measure; recovery, however, followed in a very small proportion of cases. So far as my experience goes, it affords evidence of the efficiency of the measure with regard to the immediate objects—namely, the arrest of the vomiting, purging, and cramps—but it does not afford proof of its curative efficacy. With regard to the latter, the character of the patients is to be borne in mind, nearly all who were seen in the first stage being inmates of the hospitals, and many being affected, when attacked with cholera, with some serious chronic disease, such as phthisis, Bright's disease, etc. The hypodermic injection of a solution of morphia in this disease is to be employed with circumspection. Narcotism is sometimes induced by an amount much below that which might be given by the mouth without risk. I have known a little less than a grain, given in two injections with an interval of two hours, to produce deep narcotism. The tolerance of opiates in large doses by the stomach or rectum is not a criterion of the quantity to be injected beneath the skin in epidemic cholera.

Rectal injections of brandy and a strong tea-infusion were used considerably, with apparent efficacy, in arresting the evacuations and preventing collapse. The proportions used were half an ounce of brandy and two ounces of the tea-infusion, the injections being repeated every half hour, every hour, or after longer intervals according to circumstances.

In the stage of collapse the plan of treatment indicated prior to this stage may prove not only ineffectual, but hurtful. It is still an object to arrest intestinal transudation if it continue, but to employ opiates largely for this object is not judicious with reference to the recuperative efforts of the system. The symptoms in this stage are due mainly to the damage which the blood

has sustained in the loss of its constituents from the transudation which has already taken place. Opiates may be given, and, owing to the remarkable degree of tolerance under these circumstances, they may be given in considerable doses; but much care should be observed not to induce narcotism. They should be given by either the mouth or the rectum; but never, in this stage, by the hypodermic method. Astringent remedies, if the stomach will retain them, may be added, such as tannic acid, the acetate of lead, bismuth, etc. If, however, these or other remedies provoke vomiting, they will do more harm than good. Remedies to allay vomiting may be tried—namely, the hydrocyanic acid, creasote, chloroform, etc. [The best treatment for the diarrhoea of this stage is that by warm astringent enemata, or *enterodynia*, as recommended by Cantani of Naples. After each evacuation there is injected into the bowel by means of a fountain syringe or similar apparatus a quart or more of the following solution: Boiled water or infusion of chamomile (warm), 2 litres; tannin, 5 to 10 grammes; laudanum, 30 to 50 drops powdered gum arabic, 50 grammes. If the nozzle of the tube is passed well into the rectum and the enema administered while the patient is in the recumbent position, the fluid will traverse the entire length of the colon, and may even pass beyond the ileo-cæcal valve. Excellent results have been obtained by this method, which, if resorted to early, will in a certain proportion of cases prevent the occurrence of collapse.—H.]

In a large proportion of cases after collapse has taken place little can be done with much hope of success. Even if the vomiting and purging cease recovery may not follow. The blood may have been damaged irremediably. Under these circumstances it is plain that active treatment can effect nothing. Recovery, however, in a certain proportion of cases takes place and under a great variety of treatment. It may take place when no treatment is pursued. My first case of cholera in 1849 illustrated the fact just stated. The patient was brought into hospital completely collapsed. I remained with him several hours and resorted to various therapeutical measures. At length all measures were discontinued. He was allowed to drink abundantly of cold water, under the impression that the case was utterly hopeless, and therefore the indulgence could do no harm. Much to my surprise, after an absence of several hours I found the vomiting and purging had ceased and reaction was coming on. He recovered rapidly. I have been led to doubt whether any active treatment is of use in the collapsed stage, and I cannot doubt that it is often prejudicial. The object of treatment in this stage, aside from the arrest of vomiting and purging, is to excite and aid the efforts of nature in restoring the circulation, together with the functions dependent thereon. The measures to be employed for this object are external warmth, stimulating application to the surface, diffusible and other stimulants, and alimentation.

The application of heat may be made by means of warm blankets or bottles of hot water placed near the body. The more active modes of applying heat are of doubtful propriety. I have never seen benefit from the warm bath or the application of steam or hot air. It is not desirable to excite perspiration, and if perspiration occur it should be wiped away with warm, dry cloths. Violent friction does more harm than good. The surface may be gently stimulated with sinapisms or the tincture of capsicum. Diffusible stimulants in the form of spirits and water should be given as freely as the condition of the stomach will permit, always recollecting the risk and the evils of inducing vomiting. They will be most likely to be retained if given in small quantities at a time and often repeated. If vomiting be provoked by either drastic remedies, or aliment, more or less injury is done. The ethers, stimulants such as capsicum, the essential oils, cardamom, ginger, etc., are appropriate if they be grateful to the stomach and retained. Concentrated nourishment—essence

of meat, chicken-broth, and milk—is to be given in small quantities at a time, provided the stomach will retain it. It is doubtless desirable to introduce liquid into the system as far as possible. The only objection to the free ingestion of water is the risk of provoking vomiting. Small lumps of ice should be freely allowed.

[At this stage of the disease the chief indication is to restore to the blood the fluid of which it has been drained. This may be accomplished in two ways: first, by saline transfusion; secondly, by hypodermoclysis.

If the first method be adopted, from 2 to 2½ litres of the following solution are injected into one of the veins at the bend of the arm: Distilled water, 1 litre; chloride of sodium, *pure*, 5 grammes; sulphate of sodium, *pure*, 10 grammes. This fluid, which was devised by Hayem, should be raised to the temperature of the patient's body, as determined by the thermometer inserted in the rectum, and slowly injected. The different pieces of the apparatus should, of course, be sterilized. In case of emergency a few yards of rubber tubing with a canula attached to one end and a glass funnel at the other are the only appliances needed for the performance of this simple operation. The vein is snipped with a pair of scissors, the canula inserted in the V-shaped incision thus made, and the fluid allowed to flow into the veins by gravity.

The effect of this species of transfusion is to produce immediate reaction, which in a certain proportion of cases is permanent. The operation, if properly performed, is entirely devoid of danger, and may be repeated once or oftener. As a rule, however, unless there is a decided improvement after one or two transfusions, there is no use in continuing this treatment. In 90 cases in which transfusion was performed by Hayem there were 27 recoveries. This percentage of recoveries may seem small until it is recalled to mind that the cases in which the transfusion was performed were in a very critical condition, with little or no hope of success from ordinary methods of treatment. When regarded from this point of view the results are decidedly encouraging. The chief indications for saline transfusion are coldness and duskeness of the skin, great feebleness or extinction of pulse, and urgent thirst.

Water may be added to the blood still more easily by the method known as hypodermoclysis. As indicated by its name, this consists in the subcutaneous injection of fluid, and may be readily accomplished with an apparatus composed of a hollow needle like that of an ordinary hypodermic syringe, only much larger and stronger, to which is attached a rubber tube having at its other extremity a large glass funnel or other receptacle for fluid. The operation is so simple as to be readily performed by an intelligent nurse. The funnel or bag attached to the tube is filled with the fluid raised to the temperature of 100.5° F.; a fold of skin is raised between the finger and thumb of one hand and the needle thrust well beneath it with the other. The funnel is then raised and the fluid allowed to flow under the skin by gravity. In the course of about fifteen minutes more than a quart of fluid may be thus added to the circulation. This method of treating cholera was introduced by Cantani of Naples, who recommends for injection a fluid composed of 3 per cent. of sodium chloride and 4 per cent. of sodium carbonate.

The results of hypodermoclysis are quite as striking as those of transfusion, while the greater ease with which it may be performed gives it a decided advantage over the latter.—H.]

If the patient emerge from the collapsed state, the indications are to support the system by the moderate use of stimulants and by alimentation; to restore the function of the kidneys by diuretic remedies and mucilagi-

nous drinks, bearing in mind that uræmia is one of the dangers of this stage; to restrain diarrhœa, if it occur, by anodynes and astringents; to strengthen by tonics; and to palliate by appropriate remedies the various symptoms which may arise.

[If reaction is excessive and attended with signs of cerebral hyperæmia, the body should be sponged with cool or tepid water and cold applications be made to the head. A warm bath is also of service under these circumstances, as it tends to restore the functions of the skin and kidneys and to tranquillize the circulation. The reappearance of the urinary secretion is a sign of most favorable omen, but there are no direct methods by which the suppressed function of the kidneys may be restored. It is true that Macnamara has recommended the tincture of cantharides in 10-drop doses for this purpose, but, to quote the words of Stillé, if it were not "recommended by so competent an authority its propriety might very properly be challenged."—H.]

The disinfection of the intestinal excreta in cases of cholera, as has already been mentioned, is important in view of the fact that they contain cholera germs; and during the prevalence of an epidemic this precautionary measure should be resorted to in all cases of diarrhœa.

CHAPTER IX.

INTESTINAL WORMS.

Ascaris lumbricoides.—*Oxyuris vermicularis*.—*Tricocephalus dispar*.—*Ascaris mystax*.—*Tænia*.—*Trichina spiralis*.—*Anchylostoma duodenale*.

OF the various *Entozoa* which dwell within the human body, the largest number is found in the intestines. They give rise to more or less disturbance, and are properly enough considered in connection with the functional disorders of the alimentary canal. I shall treat of intestinal worms only in so far as concerns the practical duties of the physician. The study of these and of other parasites, as belonging to comparative anatomy and physiology and as a branch of zoology, is highly interesting and has led to valuable practical results, but other points than those which relate directly to them as involving morbid conditions would be here out of place.

The intestinal worms of frequent occurrence are the *Ascaris lumbricoides*, lumbricoid or round worm, and the *Oxyuris vermicularis*, thread or seat-worm. The worm known as *Tricocephalus dispar* is sufficiently common, but is of little or no practical importance. The different species of *Tænia*, or tape-worm, are of rare occurrence in this country, but their presence constitutes an important affection. These different worms will be noticed under distinct heads. The worm called *Anchylostoma duodenale* will be noticed in connection with the cylindrical worms. As appropriately classed among the intestinal worms, because received and developed within the alimentary canal, the *Trichina spiralis* will be considered in this connection.

Ascaris lumbricoides.

With this worm every young physician soon becomes familiar. It resembles the common earth-worm. It is the most common of all the intestinal worms. It is of a whitish or yellowish color; and the body is round, fusiform, and marked by a number of fine transverse rings. The mouth is surrounded by three tubercles. The sexes are distinct. The males usually measure from four to six inches in length and the females from ten to fourteen inches.

The common lumbricoid worm inhabits the small intestine. It rarely exists in early infancy, and is most common between the ages of three and ten. It is not very uncommon in adults, but is extremely rare in old age. This species of worm is not usually solitary. In different cases the number of lumbrici varies greatly. Sometimes the number is very great, and in autopsical examinations they are occasionally coiled together so as to form balls or masses of considerable size. Cruveilhier cites a case in which more than a thousand were found after death. They are not infrequently brought into the stomach by acts of vomiting, and are ejected from the mouth. They may find their way into the nares, and they have been known to pass into the Eustachian tube, frontal sinuses, and larynx. They may migrate from the intestine into the biliary ducts and gall-bladder. In a subject dead with lumbar abscess connected with caries of the vertebræ I found a great number within the hepatic ducts, some extending along the ducts and others coiled up. They may possibly give rise to hepatic abscess. They may penetrate into the pancreatic duct. They have been found in the peritoneal cavity and in abscesses within the abdominal walls. In these cases they escape through intestinal perforations caused by ulceration or sloughing incident to other morbid conditions. It is not probable that the worms ever perforate the intestines, as was formerly supposed. They have been observed to escape from the body through fistulæ communicating with the intestinal canal.

The SYMPTOMS denoting the presence of these or other worms within the intestinal canal are obscure. A host of symptoms having little or no significance have been enumerated by writers. Nothing is more common than the passage of lumbrici from the stomach or bowels, when there have been no symptoms of disorder. The morbid effects have heretofore been greatly exaggerated. These worms, it is probable, very rarely give rise to serious results except when they migrate into the biliary or pancreatic ducts, the Eustachian tube, or the larynx; and these migrations are exceedingly infrequent. There is no foundation for the belief that they give rise to a form of fever, as implied by the term *worm fever*. They are not infrequently, in cases of fever, passed from the bowels and found in the intestine after death, but their presence is merely a coincidence. That they may give rise to convulsions, epileptic paroxysms, chorea, and other affections of the nervous system, as is generally supposed, must be considered as by no means established.

Symptoms generally regarded as denoting these worms are—colic pains, tumefaction of the abdomen, impaired appetite, excessive flow of saliva, diarrhœa, itching of the nose, swelling of the face, offensive odor of the breath, disturbed, dreamy sleep, and grinding of the teeth during sleep. It is never prudent for a physician to declare positively that a child between three and ten years of age has not worms, for he is liable to be convicted of error by the operation of a vermifuge given without his sanction; but the only readily available diagnostic proof is the presence of one or more in the stools. When more or fewer of the above-named symptoms are present a brisk

purgative may be given, the stools being examined with reference to diagnosis. If one or more worms be passed, it is proper to act as if there were others remaining. According to Davaine,¹ a microscopical examination of the feces will show the characteristic ova if lumbrici be present. He states that their ova are readily recognized, and hence the diagnosis may be made positive in this way. Practitioners in general, however, will be satisfied to base the diagnosis upon other facts.

The lumbricoid worm is propagated by ova. The body of a female lumbricus contains a vast number of eggs, estimated by Eschricht to be sixty-four millions. These ova are discharged with the feces. The observations of Davaine and others show that their vitality is retained for many months. Their ingress into the alimentary canal is probably by means of water containing them, and, finding favorable conditions in the small intestines, the production of the worms takes place. That special conditions are required may be inferred from the fact that these worms are so common in certain periods of life and so infrequent at other periods. As regards the nature of the conditions, we have no positive knowledge; but mucus in abundance is supposed to be a favorable nidus for their production.

The expulsion of lumbricoid worms is generally effected without difficulty. Beginning with a brisk purgative, which alone is sometimes sufficient, an anthelmintic remedy is to be given for several successive days. Of the various anthelmintics, those best suited for the destruction of these worms are chenopodium or wormseed, santonin, and spigelia or pinkroot. Santonin is most easily administered, and is perhaps as effective as the other articles. The dose is from 3 to 6 grains, repeated three or four times daily, given either mixed with sugar or made into *dragées* or troches. Wormseed is taken most conveniently in the form of the oil. From 5 to 10 drops may be given three times daily mixed with sugar or in an emulsion. The pinkroot has long been relied upon as an efficacious remedy. The infusion may be used, but the fluid extract of spigelia and senna is the most eligible form, the dose being from 1 to 4 drachms three times daily. Tanacetum or tansy and absinthium or wormwood are doubtless efficacious remedies. All these remedies act toxically; that is, by poisoning the worms. After two or three days a brisk purgative should be given. If with this treatment no worms be discharged, their non-existence may be inferred. If worms be brought away by this treatment, it need not be continued or repeated unless, from the continuance or recurrence of symptoms denoting disorder, it be inferred that their expulsion is not complete. The absence of the ova in the stools, according to Davaine, may be relied upon as proof positive of the absence of the worms.

With a view to prevent the ingestion of the ova of lumbrici attention should be directed to the purity of the water used as drink. Water from shallow wells in the neighborhood of dwellings and from small rivulets should be avoided. Filtration would probably prove effectual in the way of prophylaxis. Davaine states that it is not common in Paris for children and others to be affected with this worm—a fact which he attributes to the custom of using filtered water.

Oxyuris vermicularis.

This worm, called also *Ascaris vermicularis*, and commonly known as the

¹ *Traité des Entozoaires et des Maladies vermineuses de l'Homme et des Animaux domestiques*, 1860. The reader is referred to this work as treating of entozoa minutely and comprehensively. See, also, Heller, in *Ziemssen's Cyclopædia*, vol. vii., Am. ed.; Leuckart, *Die menschlichen Parasiten*, Leipzig, 1863-76; and Cobbold's *Treatise on Parasites*, London, 1879.

-, seat-, or maw-worm, inhabits the large intestine, especially the size is small, as indicated by certain of the names in common use, gth varies between two and five lines. The vermicular oxyurides exist in immense numbers, and they are sometimes voided in large balls agglomerated by mucus. They occur especially in young it they are not extremely uncommon at any period of life. I have veral examples of their occurrence in aged persons.

rms occasion pain in the rectum, tenesmus, and more especially the anus. The latter symptom, which is often due to an herpetic this situation, should always excite suspicion of the presence of tes. The itching often occurs in paroxysms, and is particularly at night. Excitation of the sexual organs frequently occurs, with ssions, and it is stated that the habit of masturbation in either ginate from this source. In girls the worms sometimes migrate gina and occasion pruritus with leucorrhœa. The diagnosis is ut difficulty. On examination of the stools the worms are seen, or less number, adhering to the feces, and on an ocular inspec-anus they may generally be discovered. It is doubtful if they o any serious disorders, but owing to the irritation which they d the loss of sleep, the general health may become more or less

ATMENT is simple and efficacious, but it may require a certain perseverance. The same anthelmintics may be employed as for the of the lumbricoid worms, given in the same way. Purgative reme-be given from time to time. In addition, enemas of either cold and water, or soap and water are to be administered once or twice se are to be continued for a fortnight or longer, until all the local lisappear. The treatment by enemas alone will frequently prove Various remedies in enemas have been advised, such as wormwood, pyreumatic oil, asafœtida, camphor, sulphide of potassium, etc. ontaining a small percentage of carbolic acid are efficacious. Infus-sia and decoction of aloes are also useful in enemas. The irrita-it inflammation about the anus which is sometimes caused by the these worms may be relieved by the application of a soothing the daily injection of a little almond or olive oil. Extreme clean-ential in the treatment. Zenker and Heller have found the eggs asite beneath the nails. The danger of auto-infection from this old be guarded against.

Trichocephalus dispar.

m, as the name trichocephalus denotes, is characterized by the hair-ance of the cephalic extremity. It is from an inch and a half to in length. The filiform cephalic portion forms about two-thirds h. As in the ascaris lumbricoides and the oxyuris vermicularis, es are distinct. The posterior or caudal extremity of the male that of the female is straight and bluntly pointed. It inhabits the cially, but is sometimes found in the colon, and very rarely in the ine. The propagation is by ova, which, according to Davaine, are gnized by means of the microscope in the dejections. The parasite quently, when sought after, in the bodies of subjects of all ages lfferent diseases. Some years ago, when engaged in examining with typhoid fever, I was led to examine the cæcum for it, and I l to find one or more. It is not positively known that its presence disorder. Barth of Paris reported a case in which death took

place with the symptoms of meningitis, and after death no lesions were found within the head, but the intestines contained an enormous quantity of worms of this species.

The foregoing species of intestinal worms belong in the class styled by helminthologists *Nematoda*, or cylindrical worms. Another worm belonging to this class was described by Bellingham under the name of *Ascaris alata*. It is the same parasite as the *ascaris mystax*, which infests the dog and cat. According to Cobbold, about seven instances of its occurrence in man have been noted. This parasite, as regards its practical importance, is in the same category with the *trichocephalus dispar*.

Tæniæ, or Tapeworms.

On the natural history of tæniæ, constituting the class *Cestoda* in helminthology, and commonly known as tapeworms, much light has been shed by the researches of Küchenmeister, Von Siebold, Leuckart, and others. Referring the reader to other works for a full account of these researches, suffice it to say that different varieties of tænia have been shown to be the cystic entozoa known as *cysticerci* and *echinococci* in a state of maturity or complete development. A *cysticercus* is an immature or undeveloped tapeworm. Different varieties of *cysticerci* are found in the solid parts of different animals, and each variety, received into the alimentary canal of another animal, and, there finding favorable conditions, becomes a perfect worm or tænia, each kind of *cysticercus* becoming a particular kind of tænia. A *cysticercus*, on the other hand, is the product of the ovum of a tænia. The eggs of the tænia, passing out of the body, finding their way into the bodies of men and other animals, and probably entering into the circulation, are transported to and fixed in solid parts, where they become *cysticerci*. The later, as long as they remain in solid parts, reach only a certain stage of development; if, however, the parts containing the *cysticerci* be eaten by another animal, they attain their complete development in the alimentary canal of the latter. Thus a particular *cysticercus* found within the liver of the rat, if eaten by the cat, is developed into the kind of tapeworm frequently found in the intestine of the latter; and the ova from this tapeworm received into the body of the rat give rise to the kind of *cysticercus* found in the liver of this animal. The ovum from the tænia of the dog, received into the body of the sheep, becomes the cystic entozoon called *Cœnurus cerebralis*, found in the brain of the latter, which, if eaten by the dog, becomes the tænia found in the intestine of this animal. These highly interesting, and in a practical view important, facts have been substantiated by observation and experiment.

The tænia or tapeworm is distinguished, as these names indicate, by its ribbon-like form. It is composed of a great number of segments or joints called proglottides, each one of which, after it attains to its full maturity, is provided with male and female generative organs. Several varieties have been found in man, but as regards medical practice the discrimination is not of much importance, the same measures of treatment being alike applicable to all. In the vast majority of cases the tænia developed in the human intestine is one of three kinds; and it will suffice to notice these.

In this country, of the three kinds of tænia, the one which has been supposed to be most common is the *Tænia solium*, or solitary tænia, so called because it is supposed always to exist singly. This is true as a rule, with some exceptions. Two or more tæniæ have been observed together, but such instances are rare. The tænia solium varies in length between four or five and thirty-five feet, the number of segments or joints

numbering from 800 to 1000. Toward the head it becomes attenuated, forming a thread-like neck of considerable length, and in this portion there are transverse markings or rugæ, but no visible joints. The joints succeeding the neck are about as long as they are broad, but lower the length is twice or thrice the breadth. From the resemblance of these joints to the seeds of a gourd the worm has been called *Vermis cucurbitinus*, or gourd-worm. The generative foramina are placed near the middle of one of the margins of each joint, and are generally alternate. The head is about the size of a pin-head, hemispherical or triangular in form, and under the microscope with a low power it is found to present four projections or suckers and a coronet of twenty-six alternating short and long hooklets surmounting a projection called the rostellum. The joints of the inferior part are constantly thrown off, and are passed almost daily by stool. These exfoliated joints contain an immense number of ova. Bennett quotes an estimate of the number of ova in the tapeworm of a cat to be 12,500,000. It is fortunate that worms are not developed from the ova within the alimentary canal!

The second variety, called *Tænia mediocanellata* (*Tænia saginata*), has not until late years been generally recognized as distinct from the *tænia solium*, and the relative frequency of its occurrence in this country has not as yet been ascertained. It is probable that here, as in England and Germany, it is more common than the *tænia solium*. The generative foramina are situated alike in both varieties, but the joints are longer and thicker, and the head has four suckers, without hooklets or rostellum.

The third variety is known as the *Tænia lata*, or broad tapeworm, reckoned by some helminthologists as a species distinct from the true *tænia*, and named *Bothriocephalus latus*. This worm is distinguished from the *tænia solium* by the breadth of the joints, which are broader than they are long, by the situation of the genital orifices, which are in the middle of the joints, and by the different conformation of the head. The head is unprovided with hooklets, and hence this and the second variety are distinguished as the unarmed *tæniæ*, while the *tænia solium* is said to be armed. The form of the head is elongated, and instead of suckers it has two lateral longitudinal depressions or fossæ; hence the name *bothriocephalus*, from *βοθριον*, a small pit. This worm may attain to even a greater length than the *tænia solium*. Like the latter, it is usually solitary. A *tænia* called *Bothriocephalus cordatus*, distinguished by the form of the head, is only known to infest the inhabitants of North Greenland.

Of these varieties of tapeworm, *tænia mediocanellata* and *tænia solium* are those commonly met with not only in this country, but in most countries. As already remarked, *tænia mediocanellata* seems to be the most common. *Bothriocephalus latus* has been observed chiefly in Russia, Switzerland, Ireland, and Japan. It is observed that this variety is likely to affect inhabitants living on the coasts of seas, lakes, and rivers, whence it has been inferred that it proceeds from a cystic entozoon existing in fish.¹ The opinion, however, is also entertained that the embryos of this worm may be taken into the system in drinking-water, and may be developed in the intestine without the intermediate stage of cystic development in the solid parts. The *tænia solium* is attributable to the ingestion of the *Cysticercus cellulosæ*, which is common in the flesh of swine. It is the presence of this entozoon in large numbers which renders pork "measly." Pork, eaten raw or partially cooked, is the source of this form of tapeworm. Thorough cooking destroys the *cysticercus*, and the development into the tapeworm does not then take place. It is a matter of observation that butchers and cooks are often affected with

¹ Küchenmeister surmises that infection occurs from eating uncooked salmon.

tapeworm, and it is stated that in Abyssinia, where the custom of eating uncooked meat prevails, nearly all persons of different ages become affected with *tænia*. The production of *tænia* in children by the use of raw meat as food in cases of so-called cholera infantum has been already referred to. The *tænia mediocanellata* is derived from a *cysticercus* found in beef. *Tænia solium* is the pork-tapeworm, and *tænia mediocanellata* is the beef-tapeworm. The frequency of one or of the other of these species in a given district bears a strict relation to the amount of underdone meaty pork or beef consumed by the inhabitants.

The habitat of a tapeworm is the small intestine. When it attains a great length it extends into the large intestine, and it has been found to reach nearly to the anus. No age is exempt from the liability to its occurrence, but in the majority of cases the ages are between twenty and forty years. It occurs oftener in females than in males. Professor Armor has reported a case in which an infant five days old passed segments of *tænia*. Two months after the birth of the child the mother was treated for *tænia*.¹ The frequency of its occurrence varies much in different countries and in different sections of the same country. The report of the military surgeons of the French army from 1840 to 1848 showed only 7 cases among 250,000 soldiers. During a practice of forty-three years I have not met with more than thirty or forty cases.

The existence of a tapeworm is not indicated by well-marked diagnostic symptoms. The symptoms attributed to it are vertigo, tinnitus aurium, disturbance of vision sometimes amounting to temporary amaurosis, pruritus at the nose and anus, salivation, disordered appetite and digestion, colic or neuralgic pains in the abdomen, and emaciation. These are symptoms which may be due to other morbid conditions, nor are these symptoms uniformly, if generally, marked in cases of tapeworm. The existence of the worm is often discovered accidentally, and in persons who prior to the discovery considered themselves perfectly well. In the case of a young female affected with sciatic neuralgia I was led to prescribe a full dose of turpentine, and the result was the expulsion of a large quantity of tapeworm, the existence of which had not been suspected. After the existence of the worm is known disorders of all kinds are likely to be referred to it, and often the imagination creates various morbid sensations. Convulsions, epilepsy, and chorea are supposed to be occasional effects, but clinical observation supplies but little data for this supposition. [The profoundest anæmia, identical symptomatically with pernicious anæmia, has been frequently observed in patients the hosts of *bothriocephalus latus*. It is not known why this particular parasite should give rise to anæmia, but the fact is indisputable. Reyher has reported a number of cases of anæmia of pernicious type in which all the symptoms ceased after the expulsion of this worm.—H.] The pathological effects of other forms of *tænia* have doubtless been greatly exaggerated. Tapeworms are almost invariably found in the intestines of dogs destroyed for experimental purposes, apparently in perfect health.

The diagnosis must rest on the discovery of detached joints or segments of the worm in the evacuations. This mode of diagnosis is always available. Segments are generally passed at short intervals, and hence it is usually not long before its existence is ascertained. If there be reason to suspect its existence before segments have been seen, a brisk purgative may be given, and this will be likely to be followed by the expulsion of a greater or less quantity. If an examination of the stools for some time, and especially after the administration of purgatives, fail to discover any portions of the worm, the physician may be satisfied of its non-existence. Persons not

¹ *Detroit Review of Medicine*, Jan., 1872.

infrequently fancy they have a tapeworm. This is one of the notions likely to be seized upon by hypochondriacs, and in some cases it becomes a fixed belief of which the mind cannot be dispossessed, becoming, in fact, an insane delusion. Several instances of this kind have fallen under my observation. A few instances are on record in which portions of the worm have been vomited.

With reference to TREATMENT a point of importance is the natural duration of the life of this parasite. It is undoubtedly long-lived. It is not uncommon for fragments to be passed at short intervals for many years. Cases have been reported in which this was observed for twelve, twenty-five, and even thirty-five years. If an interval of several months elapse without any segments having been discharged, and if subsequently they make their appearance, it is probable that a second worm has become developed. Sooner or later, the worm dies a natural death and a cure takes place spontaneously. If successive remedies have been used in such a case, the last remedy of course gets the credit of having effected a cure. For a cure to be effected with certainty the head must be expelled. The frequent exfoliation of segments is natural, and if, as an effect of a remedy or from any cause, a large portion or even all the body be expelled, reproduction by growth may take place as long as the head remains. It is, however, a matter of observation that the parasite is likely to die when the separation takes place near the head. As positive evidence of a cure the head is to be sought for; but it is not found in the larger proportion of the cases in which a cure is effected.

Of the remedies to be employed for the destruction of the tapeworm, one of the oldest, and certainly in many cases an effective remedy, is the oil of turpentine. It is most likely to be effective if given in large doses. A half ounce may be given in emulsion, with the addition of some aromatic tincture to prevent nausea, this dose being repeated every half hour until two or three ounces have been taken, or sometimes the whole amount taken at once is well borne. Strangury is an occasional result, but this is less likely to occur than when the remedy is given in small doses. After a large dose the patient feels as if slightly inebriated. This remedy, thus given, may be repeated if necessary after intervals of several days. Given in the quantity just stated, it generally acts as a purgative. Chabert's empyreumatic oil, which has been much in vogue as a remedy for tænia, is probably efficacious chiefly from the turpentine which enters into its composition, and is much more disagreeable than the turpentine alone. It is stated by Bellingham and others that turpentine, given in moderate doses and repeated for several successive days, is frequently successful.

The male fern (*Jilix mas*) is a tæniafuge, the efficacy of which rests upon the testimony of many observers of large experience. In my own experience it has proved promptly efficacious. It may be administered in powder, from half a drachm to a drachm being given in divided doses in the course of a few hours, but the oil and ethereal extract are more eligible preparations. The oil may be given in doses of a drachm either in mucilage or in gelatin capsules. The dose of the extract is from 20 to 30 grains. Dr. Alexander Fleming advises a drachm of the oil, with mucilage, to be given in an ounce and a half of sweet milk at bedtime, the dinner and evening meal of the day having been omitted. This mode of administration is advised on the supposition that milk being a favorite food of the worm, it is more effectually poisoned by imbibing the remedy in this vehicle.

Another effective tæniafuge is the kouso (*Brayera anthelmintica*), the dried flowers of a tree in Abyssinia, where tapeworm is exceedingly common. This remedy is said to be relied upon in that country. Within the past few years it has been used with much success in Europe and in this country. Half an

ounce of the powdered flowers mixed with water may be given in a dose, both the liquid and sediment being taken.

Another remedy is an emulsion of pumpkin-seeds (*Cucurbita pepo*). The emulsion is prepared by pounding two ounces of the seeds in a mortar with half a pint of water and straining through cloth. This quantity will constitute a dose which may be repeated for several days. This remedy has proved successful in the hands of a number of physicians in this country. It has the advantage of producing no unpleasant effects, being, aside from its action as a vermifuge, innocuous.

The bark of the pomegranate-root (*Punica granatum*) is another anthelmintic remedy which has been found destructive to the tapeworm. A decoction made by boiling two and a half ounces of fresh bark in a pint and a half of water until this quantity is reduced one-half is the form in which this remedy is to be administered. The whole of the quantity just named may be given in the course of a few hours. It generally produces purging, and not infrequently vomiting. [The active principle of pomegranate has been isolated by Tanret and called by him pelletierin. It has been given successfully in numerous cases, and on account of its efficacy in small dose is preferable to all the tæniifuges above mentioned. The tannate of pelletierin is the preparation usually employed. It may be administered in doses of 5 or 6 grains to adults and in 1-grain doses to children. Like all other anthelmintics, it is most efficacious when administered after fasting. A suitable vehicle for the drug is simple syrup.—H.] Kameela, the powder and hairs from the capsules of *Rottlera tinctoria*, is a powerful anthelmintic which has been found promptly efficacious in cases of tænia. The dose is from 1 to 2 drachms given in honey or thick gruel. It acts efficiently as a purgative. The remedy has been given with great success in combination with the ethereal extract of the male fern. Carbolic acid in doses of half a grain or a grain given hourly, if well tolerated, throughout the day, followed by a cathartic, has been found efficacious.

These are the most valuable of the anthelmintics which experience has shown to be capable of destroying the tapeworm toxically. The powder of tin (*pulvis stanni*), given in doses of a scruple or more, mixed with honey, has in some cases proved efficacious, probably destroying the worm by its mechanical action. It is far less reliable than the toxical remedies. Active cathartics, such as calomel and jalap, scammony, gamboge, and croton oil, occasionally succeed, their action probably being mechanical. They will generally bring away greater or less portions of the worm, but alone they are not to be relied upon for effecting a cure; that is, for destroying the worm. In conjunction with the toxical anthelmintics they are generally useful.

The success of the treatment will depend much upon accessory measures. The worm is nourished, not by nutriment sucked from the intestinal walls, but from the alimentary contents of the intestine, which enter the body of the parasite by endosmosis. An important part of the treatment, therefore, is to weaken the parasite by starvation. The patient, by way of preparation for the administration of the tæniifuge, should abstain from those articles of food which are digested in the small intestine for at least a day or two. Beef-tea or chicken-soup may be allowed freely. The treatment should be begun with a mild purgative, and the administration of the anthelmintic remedy should be followed after a few hours by a pretty active purgative. If the treatment prove unsuccessful, the strength of the patient should be restored by a return to a full diet and tonic remedies, and the same plan again repeated, employing the same remedy or selecting another. The treatment is to be repeated, allowing sufficient intervals for recruiting the strength.

until a cure is effected. It is to be borne in mind that if the greater part of the worm be expelled, although the head may not be found, the death of the worm is likely to follow, and the treatment therefore need not be repeated until the discharge of fragments is again observed.

The prophylaxis involves care never to eat meat not thoroughly cooked. In meat much underdone the cysticerci which may be contained in it are perhaps not destroyed. Purity of the water used as a drink may be an important measure of prevention. The use of filtered water is to be recommended. The meat contained in the Bologna sausages is liable to contain living cysticerci. In view of the danger of acquiring a tapeworm it is doubtful if it be ever judicious to advise raw beef or pork as an article of diet.

Trichina spiralis.

From the discovery of the *Trichina spiralis* by Paget, and its description by Owen in 1835, to a recent date, this parasite had been observed occasionally in the muscles of subjects in the dissecting-room, but in a pathological view it was not considered to have any importance. Facts, however, accumulated within the past few years have shown that the introduction and multiplication of trichinæ within the body of man may give rise to morbid effects of great gravity which often prove fatal. Much information has been obtained respecting the natural history of the parasite, the circumstances under which the human body becomes infested by it, and the morbid phenomena which characterize the disease. This information has added to the nosological catalogue a new and highly important affection known as the *trichinal* or *trichinulous* disease, *trichinosis* or *trichiniasis*.

The *trichina spiralis* belongs in the class *Nematoda*. As found in the muscles it is coiled up in a cyst containing a granular substance at first, and afterward calcareous matter. When expelled from the cyst the parasites are seen to be round worms $\frac{1}{8}$ of an inch long and $\frac{1}{16}$ of an inch in thickness. So long as they remain in the muscular tissue the worms are quiescent; when, however, they are taken into the stomach and set free by the action of the gastric liquids upon the muscular tissue and the cyst, they pass from the stomach into the intestinal canal, and immediately begin to grow rapidly, attaining to three or four times their former size; they acquire fully-developed generative organs, copulate, and, at the end of a week the female parasites contain living young in great abundance. According to Virchow, each trichina gives birth to two hundred young; Gerlach says four hundred, and Leuckart, one thousand. The young trichinæ shortly after birth penetrate the mucous membrane, and find their way rapidly to the different muscles throughout the body. They appear to select the voluntary muscles for their permanent dwelling-place. It is stated that they have not been found in the muscular walls of the heart. In other than muscular organs they are rarely found.

Trichinæ are found especially in the muscles of swine, but they have been found also in the muscles of various other animals—namely, eels, cats, rats and mice, dogs, badgers, hedgehogs, and moles. They find their way into the bodies of swine from these animals feeding upon the flesh and excrement of other animals infested with the parasites, especially rats and mice. Hence, to prevent trichiniasis in swine and in other animals which serve as food for man, it is highly important to cut off all the sources of the disease in the diet of these animals. They find their way into the alimentary canal of man chiefly from the eating of trichinous pork not subjected to processes of cooking sufficient to destroy the parasites. They are not destroyed by salting or smoking, and they may retain their vitality in roasted or broiled meat much

underdone. To effectually secure their destruction every portion of meat which is eaten should have been subjected to thorough cooking. The custom which prevails among the Germans of eating sausages and smoked hams uncooked involves a liability to the disease. It has been traced to eating pork chops which were underdone in the centre, although sufficiently cooked on the outside. Meat abounding in trichinæ may present no evidence of the fact regards the gross appearance, especially if a calcareous deposit have been taken place in the cysts which contain them; hence, trichinous meat may be sold and bought without any suspicion of its being unwholesome. The only reliable evidence of the presence of trichinæ in the meat procured for food is afforded by microscopical examination. The trouble, however, of such an examination precludes its being generally resorted to as a means of protection. Moreover, a microscopical examination of a few specimens is not adequate to determine that trichinæ are not present. They may not be found in the few specimens examined, although present in other portions. Hence this test is reliable only in a positive not in a negative point of view.

After becoming encysted in the muscles the trichinæ retain their vitality for an indefinite time. In one case trichinæ were found encysted and alive in portions of muscle attached to a cancerous tumor removed from a patient. The previous history of this case showed conclusively that the patient was affected with trichiniasis twenty-four years before the operation.¹ The flesh of animals, therefore, which have been affected with trichiniasis will ever afterward be likely to contain living trichinæ. Moreover, the flesh of a single trichinous animal may produce trichiniasis in a very large number of persons, so that the disease in its prevalence may present the character of an epidemic. Muscular trichinæ, however, may after a time become completely calcified, in which case they are innocuous.

The clinical history of the disease caused by trichinæ is highly important with reference to an early diagnosis. The primary symptoms relate to the alimentary canal, and are due chiefly to the perforation of the mucous membrane by the newly-produced worms. Abdominal pains, vomiting, and diarrhoea characterize the first stage of the disease. These symptoms occur within ten days after the ingestion of trichinous meat; that is, as soon as the young worms have been produced and become developed so as to begin to migrate toward the muscles. It is not difficult to understand that the aggregated punctures of the mucous membrane by these parasites should occasion notable disturbance when it is considered that the trichinæ which have been found to be contained in a half pound of meat may be sufficient to give birth in a few days to a brood numbering 30,000,000. It is stated that peritonitis may be produced by the passage of worms into the peritoneal cavity.

The secondary symptoms relate to the muscles. Pains resembling those of myalgia are occasioned by the entrance of the trichinæ into the muscles. Certain of the muscles become contracted in some cases, and their extension occasions great suffering. Constitutional disturbance more or less marked accompanies both the primary and the secondary symptoms. The general symptoms are not unlike those of typhoid fever, for which the disease is likely to be mistaken. The temperature in the axilla varies between 101° and 106°. Oedema of the face or lower extremities often occurs, and sometimes there is anasarca. Sweating is generally prominent as a symptom. Death takes place in a certain proportion of cases after a protracted period of suffering and exhaustion, being often preceded by coma. It is stated that life in some cases is destroyed by the impairment of the respiratory muscles from the presence of the parasites. Aphonia is a symptom which exists in some

¹ *Medical News and Library*, Philadelphia, May, 1866.

ses, attributable to the presence of trichinæ in the muscles of phonation. Deafness may be caused by trichinæ in the stapedius muscle. The danger, *terris paribus*, is proportionate to the abundance of trichinæ generated within the alimentary canal. If the number be not sufficient to cause death in the amount of local and constitutional disturbance which they occasion, recovery takes place very slowly, the illness lasting for several weeks or even months. The trichinæ become encysted in the muscles, thereafter remaining inert.

Diarrhoea and abdominal pains, followed by muscular pains, together with more or less constitutional disturbance, should excite suspicion of this disease. Inquiries respecting food should be instituted, and if any portion of the suspected meat remain, it should be examined microscopically. The diagnosis may be made still more complete by harpooning some one or more of the painful muscles and obtaining portions sufficient for examination with the microscope. Davaine suggests that the presence of trichinæ in the stools may be ascertained, and the diagnosis in this way rendered positive. If clinical observation should establish the availability of the latter method of arriving at a diagnosis, it would have this advantage—namely, the existence of the disease may be positively ascertained before the trichinæ migrate from the alimentary canal. The practical importance of making the diagnosis thus early is sufficiently obvious.

It is evident that the treatment of this disease to be effective must be employed while the worms are in the alimentary canal. Hence, the importance of an early diagnosis. It remains to be ascertained whether treatment can be effectively employed in this stage, and to determine the measures most likely to prove effective. The object is either the destruction of the worms or their expulsion from the intestines. Cathartics are indicated for the latter object, but clinical experience has yet to show what toxical anthelmintics are best suited to destroy this parasite. Benzine has been found by Mosler to destroy the trichinæ in the intestinal canal, when given in doses which are well borne by the patient. Mosler's method of treatment with this remedy is to have a mixture consisting of two drachms of benzine, an ounce of licorice-juice and mucilage of gum-arabic, and four ounces of peppermint-water. Of this mixture a tablespoonful is to be given every one or two hours. This remedy, however, has not proved efficacious; but it is to be considered that the diagnosis is rarely made prior to the emigration of the parasites from the alimentary canal. The carbolic acid is a remedy which should be tried with a view to the destruction of the worms in the intestinal canal. After the trichinæ have left the intestines the opportunity for destroying or expelling them has passed. Recovery now depends on the ability of the system to endure them until they become encysted. Measures to palliate pain, to restore disordered functions, and to support the powers of life are indicated, and the success of the treatment will depend on the judicious employment of measures for these ends.

The prevention of this disease is the great practical benefit to be derived from its discovery. The mode of prevention is sufficiently simple—namely, abstaining from meat, especially the flesh of swine, not thoroughly cooked. The process of smoking, pickling, or salting cannot be relied upon for the destruction of this worm. Uncooked sausages cannot be eaten without danger. Heller states that the parasite is destroyed by a temperature of 155° F.

Anchylostoma duodenale.

This worm was discovered by Dubini in Milan in 1838. Its relation to a severe form of anæmia which prevails in Egypt was first made known by

Griesinger in 1851. The disease to which this parasite bears a causative relation has received various names, of which the following are the most important: Egyptian chlorosis, anchylostoma disease, anchylostomiasis, tropical chlorosis, the anæmia of the workers in tunnels, etc. The anchylostoma disease is common in Egypt, in Brazil, and in some other tropical countries. It has also been observed in Italy, and was not uncommon among the workmen engaged in building the St. Gothard tunnel. It has recently been observed among workmen in coal-mines and in brickyards in Belgium, also in the neighborhood of Cologne, and occasionally in other parts of Germany. It has been thought that the parasites are brought to these places by Italian workmen. This parasite has been found also in certain cases of geophagia. No cases of the disease have been described as occurring in this country.

The anchylostoma duodenale belongs to the family Strongylidæ of the order of nematoid worms. It is also called strongylus or dochmius duodenalis. It is found in the upper part of the small intestine in man. The body of the worm is round and thread-like. The length of the female is from 6 to 18 mm., that of the male from 6 to 10 mm. There is an average of about three females to one male present. The conical pointed head is bent backward, and presents a mouth surrounded by a horny capsule, and possessing on the ventral side four hook-like teeth and on the dorsal side two vertical teeth. The eggs of anchylostoma are oval in shape, from 44 to 67 μ long and from 23 to 40 μ broad. They undergo the first segmentation within the intestine. Outside of the body, in muddy water and under artificial cultivation at a temperature of from 25° to 30° C., embryos develop and escape from the eggs, and then become encysted as larvæ in a clear chitinous layer. These larvæ or embryos when taken into the human intestine develop into the mature worms. The anchylostoma worms do not multiply within the intestine, so that the number there present corresponds to the number of embryos which have been swallowed.

The anchylostoma duodenale bites with its claw-like hooks or teeth the intestinal mucous membrane, and may penetrate to the submucous coat. Here it sucks the blood from the intestinal vessels. The female worms are those found most gorged with blood. Sometimes the living worm is found rolled up in the substance of the mucous or the submucous coat in a little cavity filled with blood. The parasite leaves behind an ecchymosis of the size of a pea with a white spot in the centre, presenting a little hole through which blood can ooze.

The anchylostoma duodenale proves dangerous both by causing digestive disturbances and by withdrawing blood from the body. The leading symptom of the anchylostoma disease is anæmia, which may become as profound as pernicious anæmia, and in fact has often been mistaken for pernicious anæmia. When a large number of anchylostoma embryos are introduced once or rapidly into the intestine, the anæmia develops acutely; and when they are introduced more slowly the anæmia is chronic in its development. Other symptoms are colicky pains in the abdomen, nausea, vomiting, constipation alternating with diarrhœa, and abnormalities of the appetite. The stools may or may not contain blood.

The DIAGNOSIS is based upon finding the eggs or the mature worms in the feces. These are present after the administration of a brisk cathartic. The number of eggs found gives a clue as to the number of worms present. The degree of anæmia is not always proportionate to the number of worms present.

The DURATION of the anchylostoma disease varies between a few months and several years.

The PROGNOSIS depends upon the degree of the anæmia and the obstinacy of the diarrhœa and other digestive disturbances. A fatal termination is not

uncommon when the disease is left to pursue its own course. Nevertheless, the disease may cease spontaneously by the passage or death of the parasites. The anchylostoma eggs are sometimes found in the feces of those who present no symptoms of disease.

The TREATMENT consists in the administration of anthelmintics and of iron. An anthelmintic of great repute in Brazil against this parasite is doliarina, a preparation made from the juice of the tree *Ficus doliaria*, and mixed with aromatics and some form of iron. About a drachm of this is given three times daily. The ethereal extract of male fern in large doses has also been found useful in expelling the parasites. Thymol in form of powder has likewise been recommended.

Animals not entozoic, such as snakes, slugs, and lizards, are not infrequently exhibited to physicians as having passed from the alimentary canal. It is a popular notion that they may live and grow indefinitely within the stomach and intestine and give rise to a variety of morbid symptoms. In the great majority of cases the statements with respect to the passage of these animals are simply falsehoods, proceeding generally from a morbid exaggeration of that craving to become objects of curiosity and interest which enters largely into the mental constitution of many persons. In some cases, however, the statements are honestly made, persons being deceived. Prof. Dalton performed a series of experiments to ascertain the duration of life of the common garden slug (*Limax agrestis*) and the water-lizard (*Triton millepunctatus*) after having been introduced within the stomach of a dog. The former were found completely dead at the end of nine and a half minutes, and no traces of them were discoverable when the dog was killed an hour after their introduction. The lizards were found perfectly dead and about to undergo the digestive process at the end of fifteen minutes.¹ It is safe to set down most of the cases referred to as cases of either self-deception or imposition. Maggots, however, have been known to be discharged from the nasal cavity, the mouth, and the rectum. They may be developed in the nasal cavity from ova inhaled.

CHAPTER X.

DISEASES OF THE PERITONEUM.

Acute Diffuse Peritonitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Circumscribed Peritonitis.—Chronic Peritonitis.—Hydro-peritoneum.

THE peritoneal cavity, like other serous cavities, has been generally regarded as a large lymph-sac lined with a single layer of flat, polygonal cells called endothelium. (For a different conception of the nature of this cavity the reader is referred to p. 23.) It communicates by means of minute openings, called stomata, between the endothelial cells with the lymph-spaces in the subserous connective tissue. Liquids and small particles are readily absorbed from the peritoneal sac by the adjoining lymphatic canals. By this

¹ *American Journal of Medical Sciences*, April, 1865.

free communication with the lymphatic system the peritoneum readily receives infectious and otherwise deleterious substances which may be present in adjoining organs. This disposition favors the propagation of inflammation from these organs to the peritoneum. Peritonitis may be acute or chronic, diffuse or circumscribed. It will be convenient to consider separately acute diffuse or general peritonitis, circumscribed or partial peritonitis, and chronic peritonitis. Some writers divide the disease into several varieties according to its different causes or to the circumstances under which it is developed. It will suffice to notice these diversities under the head of Causation. Puerperal peritonitis is an important variety presenting certain peculiarities, but it does not fall within the scope of this work to consider this form fully or separately. It is treated of at length in works on obstetrics and on the diseases of women.

Acute Diffuse Peritonitis.

ANATOMICAL CHARACTERS.—The pathological changes are essentially the same as in inflammation of other serous membranes. The intestine, as a rule, is distended with gas. The inflammation usually begins at one spot, and extends with more or less rapidity over the entire membrane. The inflammatory changes are usually most marked at the starting-point, and are elsewhere more intense in certain places than in others. At first there is redness due to congestion and ecchymoses. The serous surface loses its normal lustre, and soon it is coated with a thin, grayish layer of fibrillated fibrin, which at first contains few cells, but afterward becomes richly infiltrated with pus-cells, and then assumes a greenish-yellow color. The exuded fibrin causes the coils of intestine to become agglutinated to each other, to neighboring viscera, and to the abdominal walls. Together with the exudation of fibrin there is an effusion into the peritoneal cavity of more or less serum containing flocculi of fibrin and some pus-cells. The subserous tissue is swollen and oedematous, and contains pus-cells, usually in swarms about the veins. The other coats of the intestine may be somewhat altered. The muscularis is usually oedematous, and, especially in cases of puerperal peritonitis, there may be inflammation of the mucous membrane. While the chief source of pus-cells is from the blood, there is sufficient evidence that the endothelial cells lining the peritoneum likewise take an active part in the inflammatory process. They become swollen, granular, multinucleated, and by their proliferation produce young cells.

Different cases of peritonitis vary greatly as to the quantity and character of the inflammatory products. These products are fibrin, serum, and pus-cells, mixed with a certain number of red blood-corpuscles. According to differences in causation and in individuals, sometimes one and sometimes another of these products preponderates. In some cases the exudation is chiefly fibrinous, in others chiefly serous, and in others purulent. Again, the exudation may be described as sero-fibrinous, sero-purulent, fibrino-purulent, etc. Peritonitis with fibrinous exudation and with but little fluid is sometimes called dry or adhesive. In some cases the peritoneal cavity is distended by a large quantity of serum. Such cases are generally secondary to ascites. In the majority of cases the exudation may be described as sero-fibrinous; that is, the peritoneal surfaces are coated with fibrin, and the cavity contains a moderate amount of serum rendered somewhat turbid by admixture with fibrin and pus-cells. Purulent effusions are also frequently met with. All grades of transition occur between the moderately turbid serum just described and thick creamy pus. Peritonitis due to perforation, to traumatism, and to puerperal fever and other infectious processes is generally purulent. In sep

tic peritonitis the exudation may be foul-smelling and ichorous. In very rare cases it has a colloid consistence. Not infrequently it has a reddish or brownish tint from admixture with blood, but a truly hemorrhagic exudation belongs to certain forms of chronic rather than to acute peritonitis. It is not rare to find collections of serum or of pus encysted in different parts of the peritoneal cavity by means of fibrinous or of old organized adhesions. In connection with these collections of pus there have been observed suppuration and ulceration of portions of intestine with which the pus is in contact, and even perforation from without inward (ulcerative peritonitis).

If peritonitis terminate in recovery the serum is absorbed, and the fibrin, having undergone molecular disintegration, is likewise absorbed. Large collections of pus cannot be absorbed, but the pus may lose its watery constituents, become inspissated, and be converted into a kind of cheesy mass in which lime-salts may be deposited. New connective tissue in the form of adhesions and of thickening of the serous membrane is a result of peritonitis. The method of formation of this new tissue resembles that already described for inflammation of the pleura (p. 25). There may be adhesions of the coils of intestine to each other, to the solid viscera, and of the opposing parietal and visceral layers of the membrane. These adhesions may be innocuous, but they may also be the cause of serious and even fatal consequences. In the spaces or loops formed by bridges of newly-formed tissue portions of intestine are liable to become strangulated. The contraction of the new fibrous tissue may lead to constriction of the intestine. Coils of intestine may be so bound together by adhesions that their peristole is greatly impaired. In cases in which the cause of the peritonitis is not evident it is always necessary to search carefully for some lesion to which the inflammation can be referred. The presumption is in any given case against a primary peritonitis. A causative lesion will be found in most cases in some organ or part within the abdominal cavity, such as perforation of a hollow viscus, hernia, typhilitis, perityphlitis, and inflammation of other parts adjoining the peritoneum, especially the female generative organs.

CLINICAL HISTORY.—Acute peritonitis is sometimes developed gradually. Abdominal pain and soreness, progressively increasing, may be felt one, two, or three days before the local and general symptoms are sufficient to show the existence of the disease; but in most cases the attack is abrupt and the disease is quickly declared. The disease is often in these cases ushered in by a chill. Pain is usually a marked symptom. Beginning at a particular point, it extends over the whole abdomen. It is burning or lancinating in character. It is increased at times so as to constitute marked exacerbations, and not infrequently in these exacerbations the character of the pain is that of spasm or colic. Acute pain is produced by a deep inspiration. The respirations are usually shortened, and by way of compensation increased in frequency. The movements of the diaphragm are restrained, and those of the ribs proportionately increased; the breathing, in other words, is costal. Acts of coughing and sneezing occasion intense pain. Movements of the body are painful. The degree of suffering from pain varies in different cases. It is generally great, often extreme, occasionally moderate or slight; and this symptom may be wanting. Tenderness on pressure over the abdomen is usually marked. This symptom is very rarely wanting. The tenderness is often such that the slightest pressure is painful, but the degree of tenderness varies considerably in different cases. The pain and tenderness are frequently most marked in a particular circumscribed portion of the abdomen. These symptoms continue during the course of the disease. Owing to these symptoms the patient often lies upon the back, with the knees and thighs raised,

in order to lessen the tension of the abdominal muscles and to relieve the abdomen of the weight of the bedclothes. This decubitus, however, is by no means constant. The patient may lie on the side with the knees and thighs flexed, or even on the back with the lower limbs extended. More or less tympanites is generally present, due to paralysis of the muscular coat of the intestine. The abdomen is often greatly distended and tense; and this condition persists during the course of the disease. The abdominal distension offers a mechanical obstacle to the descent of the diaphragm, and thus increases the dyspnoea, which if great is accompanied by cyanosis. The distension may be sufficient to displace the heart and to push the liver upward. If the tympanites be not great, the abdominal muscles, especially the rectus muscle on either side, are usually notably rigid and resisting. The bowels, as a rule, are constipated, but the exceptions to this rule are not very infrequent. Constipation sometimes exists at first, diarrhoea subsequently occurring, and occasionally diarrhoea exists at the outset. The latter symptom is most frequent in cases of puerperal peritonitis, in consequence of the coexistence of inflammation of the intestinal mucous membrane. Vomiting is a frequent, and in some cases a prominent symptom. The vomited matter consists of mucus and the contents of the stomach, and afterward of bile, which often has a notably green color. This grass-green or spinach color is, however, not characteristic of peritonitis. The acts of vomiting occasion great pain. In the latter part of the course of the disease the contents of the stomach are ejected by regurgitation rather than by vomiting. Thirst is usually urgent. Obstinate and painful singultus is a not infrequent symptom.

The temperature of the body is more or less raised, but there is much variation in different cases as regards the degree of pyrexia. In some cases there is but a moderate increase of temperature; and in other cases there is hyperpyrexia. There may be considerable variation in the same case during the course of the disease. The temperature sometimes falls to nearly the normal shortly before death. The pulse is more or less accelerated. It often becomes quite frequent, numbering 120 or 130 per minute; but in some cases the acceleration is moderate. It is generally small, and sometimes hard or wiry. The sense of prostration is considerable or great. Perspiration is liable to occur. The countenance denotes the gravity of the disease, and the expression is haggard, pinched, and anxious. In some cases the upper lip is elevated and drawn tightly over the teeth. This appearance is characteristic, and when present it points to the disease, but it is by no means uniformly present.

Difficulty in micturition is a frequent symptom, due in part to paralysis of the muscular tunic of the bladder in consequence of inflammation of its investing membrane, and partly to loss of power over the abdominal muscles in consequence of the abdominal distension. Moreover, the pain occasioned by the effort to micturate leads the patient to postpone it as long as possible. Retention of urine, requiring the use of the catheter, is not uncommon. The urine is high-colored, and throws down a lateritious deposit of urates. Pain in the penis is a symptom in certain cases of peritonitis. This pain is sometimes extremely intense. In some cases there is priapism with intense venereal desire.

The intellect in cases of acute peritonitis is generally not disordered. Slight delirium sometimes occurs, especially in fatal cases, toward the close of the disease.

PATHOLOGICAL CHARACTER.—Acute peritonitis, as regards pathological character, does not differ essentially from other acute inflammations of serous membranes.

CAUSATION.—Acute diffuse inflammation of the peritoneum, exclusive of puerperal peritonitis, is not a frequent disease. The liability of the peritoneum to become inflamed is very much less than that of the pleura or the pericardium—a fact not easily explained. In the great majority of cases peritonitis is incidental to some other affection of the abdominal viscera. The most frequent cause, exclusive of its occurrence in childhood and of the cases in which it is produced by traumatism, is perforation of the alimentary canal. Perforation of the ileum is incident to the intestinal lesions of typhoid fever, and peritonitis thus produced is one of the occasional events pertaining to the clinical history of that form of fever. The intestinal ulcerations which occur in certain cases of phthisis sometimes, although very rarely, lead to perforation, and also other ulcers situated in either the small or large intestine. Perforation from ulceration or sphacelation of the extremity of the appendix vermiformis of the cæcum is not of very rare occurrence. (Vide p. 420.) Perforation of the stomach and of the duodenum is an occasional event in cases of gastric and duodenal ulcer. Whatever be the seat of the perforation, the gaseous and other contents of the alimentary canal escaping into the peritoneal sac, peritonitis becomes at once developed. The escape of bile from rupture of the gall-bladder or of the cystic, hepatic, or common duct gives rise to peritonitis. Other causes are the discharge of pus into the peritoneal cavity from hepatic, ovarian, or other abscesses, rupture of the urinary bladder or ureter, and the evacuation of hydatid cysts. Inflammation, at first local, may become general, as in certain cases of intussusception and strangulation of intestine, of typhilitis, and perityphilitis without perforation. Injections into the cavity of the uterus have been known to give rise to the disease, the liquid injected passing into the peritoneal cavity through the Fallopian tubes. In certain cases of puerperal peritonitis the inflammation begins in the uterus and is propagated to the peritoneum. The disease may be produced traumatically by accidental wounds of the abdominal walls and violent contusions. It may be caused by surgical operations which involve opening of the peritoneal cavity in cases of ovariectomy, of laparotomy in cases of obstruction, etc. It sometimes follows trepanation, very rarely, however, except in cases in which the kidneys are diseased. It occurs in intra-uterine life—a fact which Sir James Simpson was the first to observe. The extension of inflammation from the umbilical vessels to the peritoneum explains the occurrence in some instances of infantile peritonitis.

Acute peritonitis is one of the local affections incident to the morbid conditions of the kidneys collectively called Bright's disease. In two cases under observation it was developed in connection with acute articular rheumatism, the patient recovering in each case after a short duration of the disease. Exposure to cold may give rise to it. I have known its occurrence to be attributable to this cause. It has been observed to occur not infrequently in the Northern States among laborers employed in the winter and spring to repair water-wheels damaged by ice, this occupation requiring them to work standing in water.

Occurring as an epidemic affection in childhood, it doubtless proceeds from a special cause. During the prevalence of puerperal peritonitis, epidemic erysipelas has been observed to prevail, showing some pathological relationship between the two affections.

DIAGNOSIS.—The diagnosis of acute diffuse peritonitis is not difficult in cases in which its characteristic features are well marked, as they are in the majority of cases. These features are sometimes obscure or wanting, and it is then liable to be overlooked or to be confounded with other affections.

From acute enteritis it is distinguished generally by a greater degree of pain, greater frequency of the pulse, more tenderness on pressure over the abdomen, more tympanites, rigidity of the abdominal muscles, and the evidence on all sides of a graver malady.

It is sometimes mistaken for functional colic. The pains in some cases of peritonitis are like those of colic; but colic lacks the continuous pain, the abdominal tenderness, the muscular rigidity, the tympanites, the pyrexia, the frequency of the pulse, prostration, etc. of acute peritonitis. The symptoms, however, may not be immediately developed in peritonitis, and little delay may therefore sometimes be necessary in arriving at a positive diagnosis.

Myalgia (muscular rheumatism) affecting the abdominal muscles may give rise to certain of the local symptoms of acute peritonitis. Instances, however, of myalgia limited to these muscles are rare. The diagnostic points are as follows: In peritonitis movements of the body occasion pain over the whole abdomen, whereas in myalgia the pain is limited to certain muscles, and perhaps confined to one side of the abdomen. The same is true of tenderness on pressure. Moreover, in peritonitis the pain from pressure is proportionate to the amount of pressure, but in myalgia deep, firm pressure may be made without augmenting the pain. These are diagnostic points pertaining to the local symptoms, but the general symptoms present in acute peritonitis are wanting in the so-called muscular rheumatism.

Lumbo-abdominal neuralgia with hyperæsthesia of the abdominal walls or integument sometimes simulates closely peritonitis as regards certain local symptoms. The pain may be severe, the tenderness great, the decubitus on the back with the thighs and knees flexed, and not infrequently there is more or less tympanites. Cases presenting these symptoms are not uncommon. The patients are generally women, and they manifest more or less of hysterical phenomena. The general symptoms of acute peritonitis, frequency of pulse, prostration, etc., are wanting in these cases; but attention to certain points connected with the local symptoms will suffice for the differential diagnosis. The tenderness in the neuralgic affection is more superficial; the patient shrinks from the slightest touch, but firm, prolonged pressure with the open palm is often well borne, and may even afford relief, whereas in peritonitis the pain is always proportionate to the amount of pressure. The muscular rigidity of peritonitis is wanting.

I have known acute peritonitis to be mistaken for sporadic cholera in a case in which vomiting and purging occurred early and were prominent symptoms. In the exceptional cases in which these symptoms are sufficiently prominent to suggest that affection, the error of diagnosis is to be avoided by finding, associated with the vomiting and purging, the local symptoms of peritonitis—namely, pain, tenderness, tympanites, and muscular rigidity, together with general symptoms denoting an inflammatory affection—symptoms not belonging to the history of sporadic cholera.

Acute peritonitis is sometimes remarkably latent, the local symptoms, usually so strongly marked, being obscure or wanting. Pain and tenderness may be slight or even absent. Muscular rigidity in such cases may be a very valuable diagnostic symptom. As regards occasional latency, this disease resembles other inflammations of serous membranes—namely, pleuritis and pericarditis. Pain and tenderness may be obscure in consequence of the coexistence of other affections which occasion delirium or blunt the perceptions of the patient, and from the absence of these local symptoms peritonitis may be overlooked. In some cases of peritonitis produced by perforation—in the course of typhoid fever, for example—the manifestations of pain and tenderness may not be sufficient to direct attention to the abdomen. In such cases

other local in conjunction with general symptoms must be relied upon in the diagnosis. Certain physical signs may enter into the diagnosis of peritonitis. There is not infrequently liquid effusion sufficient to be recognized by percussion and palpation. (Vide Diagnosis of Hydro-peritoneum.) A peritoneal friction sound may be heard by auscultation over the liver.

It is desirable in cases of peritonitis to determine whether the disease be idiopathic or dependent on some one of the various local circumstances which in the majority of cases stand in a causative relation to it. In consequence of the relative infrequency of idiopathic peritonitis the probabilities in any case are in favor of the existence of some one of these causative circumstances. Developed in the course of typhoid fever, it generally, but not invariably, proceeds from perforation of the intestine. If developed in a case of pulmonary tuberculosis accompanied by diarrhœa, chronic peritonitis not preceding its development, perforation connected with intestinal ulceration is the probable cause. Perforation of the stomach is probable if the peritonitis occur suddenly in a case presenting the symptoms of gastric ulcer. Perforation of the intestine, connected with latent ulceration, is to be very strongly suspected whenever the affection is developed suddenly, without any appreciable cause, in a person apparently in health; and if the pain and tenderness first occur in the neighborhood of the cæcum, and continue most marked in this region, the seat of the perforation is probably the appendix vermiformis. In cases of perforation gas usually escapes into the peritoneal cavity. Its presence here gives rise to intense tympanitic resonance on percussion, extending over the liver and taking the place of hepatic flatness. Tympanitic resonance over the liver, however, cannot be considered as proof of the presence of gas in the peritoneal cavity, inasmuch as this resonance is found not infrequently when the transverse colon is much distended with gas or when this portion of the intestine is pushed upward above the lower margin of the liver; but persistent hepatic flatness is proof almost absolute against perforation. Clinical observations, in my experience, substantiate this statement. In a cadaver in which the intestines are nearly free from gas, and even when the muscular walls of the abdomen are notably stiff from cadaveric rigidity, the injection of a small quantity of air into the peritoneal cavity suffices to render the resonance over the liver tympanitic. This experiment I have repeatedly performed.¹ Perforation of the ureter may be strongly suspected if the sudden development of the disease have been preceded by symptoms denoting obstruction from calculus or some other cause. In like manner, perforation of the ductus communis choledochus is the probable cause if symptoms denoting the impaction of gall-stone in this duct have preceded. The disease is attributable to intussusception or internal strangulation of the intestine when preceded and accompanied by symptoms denoting these causes of obstruction of the bowels. Its connection with renal disease is to be determined by an examination of the urine for albumen and tubular casts. Finally, if evidence of the existence of any of the causative circumstances referred to be wanting, and the disease be fairly attributable to exposure to cold, it is to be considered as idiopathic.

PROGNOSIS.—Acute general peritonitis is always a grave disease, involving danger to life. In the majority of cases the danger is greatly enhanced

¹ Vide paper by the author in *Transactions of the Medical Society of the State of New York*, entitled "On the Physical Diagnosis of Peritonitis with and without Perforation of the Alimentary Canal," 1882; also article by the author, entitled "On the Persistence of Flatness on Percussion over the Liver, as Proof that Acute Diffuse Peritonitis is not associated with Perforation of the Stomach or Intestine," in the *Medical News*, Jan. 17, 1885.

either by the circumstances on which the development of the disease depends as, for example, intestinal perforation, or by coexisting affections, such as renal disease. We have no data for determining the amount of intrinsic tendency to death belonging to simple idiopathic peritonitis. There is reason to believe that the rate of fatality in all cases depends much on the mode of management. Judiciously treated in uncomplicated cases, the prospect of recovery is good. In complicated cases—including under this head cases in which the disease is connected with gastric or intestinal ulceration, Bright's disease, etc.—the prognosis is always very unfavorable. Under certain circumstances the disease runs rapidly to a fatal issue. It may destroy life within a few hours if developed as a result of perforation. Recovery, however, is not impossible in cases of perforation, provided the opening be not large and if closure be quickly effected by adhesions around it. The average duration in fatal cases is from five to six days.

The mode of dying is by either rapid or slow asthenia. An unfavorable progress of the disease is denoted by a progressive increase of the feebleness and frequency of the pulse, progressively increasing prostration, coldness of the extremities, cyanosis, hiccough, regurgitation, etc. On the other hand, a favorable progress may be inferred from improvement as regards the general symptoms just referred to, together with diminution of the tympanites and muscular rigidity of the abdomen. Convalescence is generally slow, more or less tenderness and colic pains persisting during the progress toward recovery.

TREATMENT.—The treatment of this disease, as inculcated and generally adopted of late years in this country, is in striking contrast with that formerly pursued. The change consists—*first*, in the disuse of bloodletting and cathartics; and *second*, in relying mainly on the use of opium. Governed by the general principles which should regulate the employment of bloodletting in acute inflammations, the indications for this measure are not present in peritonitis, a disease which tends to destroy life, sometimes very quickly, by asthenia. Bloodletting has been much employed in the treatment of this disease, and clinical observation has abundantly shown that it is not, to say the least, a curative measure. It is a measure which must do either good or harm in a disease like this, involving always not a little danger to life; and if it do harm instead of good, the amount of harm, even if not large, may bear heavily on the result. Cathartics also have been much employed in the treatment of this disease. Not only are they devoid of curative efficacy, but they are pernicious. An important point in the treatment of an acute inflammation of any part is to secure for the part as complete rest as possible. The friction incident to the peristaltic movements tends to prolong and increase the inflammation in peritonitis. An object of treatment is the arrest of these movements, thus securing rest for the inflamed membrane. Cathartics not only conflict with the means for effecting this object, but they aggravate the inflammation by increasing the peristaltic movements. Moreover, they are objectionable on the same score as bloodletting and other depletory and depressing measures. Clinical observation furnishes no evidence of the usefulness of cathartics in the treatment of acute peritonitis. On the other hand, it has occurred to me, as to others, to see the intensity of the inflammation reproduced by the too early administration of a cathartic when the disease appeared to be progressing favorably, the patient's life apparently being lost in consequence. Cathartics, then, should not enter into the treatment of this disease. The bowels should be allowed to remain constipated, if evacuations do not spontaneously occur, during the career of the disease, even if this period be a week or more. In pursuing this course the physician

must expect in some cases to encounter the importunities of the patient or friends for medicine to open the bowels. If the patient suffer from an accumulation of feces within the rectum, its contents may be cautiously removed by repeated simple injections. Much relief, if tympanites be great, is sometimes obtained by the introduction into the rectum of a flexible tube, which allows the escape of gas.

[Of late years, saline cathartics have been much employed in the treatment of peritonitis, the objects being to deplete the vessels of the inflamed serosa and to remove toxic products by intestinal drainage. If the intestinal wall is intact the inflammatory process may perhaps be favorably modified by this method, but if perforation exists the danger of the discharge of feces into the peritoneal cavity is greatly increased by it, the effect of the saline being to liquefy the intestinal contents and increase peristaltic action.]

Dr. Maurice H. Richardson has recently called attention to the dangers attendant upon the use of these drugs, especially in cases of perforative appendicitis.

When the peritonitis, from being local, has become general, salines are of no use whatever. As Richardson remarks, "In a completely established general peritonitis from whatever cause, with distention, vomiting, and obstipation, in my experience salines accomplish absolutely nothing."¹—H.]

An important object effected by the use of opiates is the arrest of the peristaltic movements; and this is a special object in this disease, but opiates are also useful, as in other inflammations, by rendering the system more tolerant of the local affection. The latter is also an object in the treatment. With reference to both these objects opiates are to be given in doses sufficient to produce certain effects. Relief of abdominal pain is evidence that the first object is effected. The doses, therefore, should be sufficient to produce this effect. The pain is to be relieved as quickly as possible, and the return of pain prevented by repeating the required doses at proper intervals. The success of the treatment will depend much on its being begun early in the disease. Time should not be wasted by delay for any preliminary measures. The treatment should begin with a full dose, the amount being regulated by the intensity of the pain. For an adult a quarter or a half of a grain of a salt of morphia or an equivalent dose of some other form of opiate may be given at once. In two or three hours the effect of the first dose can be appreciated. If the patient be not then free from pain, another dose is to be given, the dose being increased or diminished according to the degree of pain. And during the course of the disease the opiate is to be repeated, if required, at intervals, in doses sufficient to prevent return of pain. Narcotism is to be avoided. In order to avoid this the physician is to observe the effects of the doses as regard somnolency, contraction of the pupil, and diminished number of respirations. Judgment and careful watching are important, lest narcotism be produced. The somnolency from the opiates should never become so great that the patient cannot be easily aroused. The respirations should not be reduced below twelve per minute. If, as not infrequently happens, they are found below this number or irregular, the intervals between the doses are to be lengthened or the doses diminished. In carrying out his method of treatment it is desirable that the physician should see the patient frequently. If this be impracticable, as it often is in country practice, the administration of the doses must be entrusted with minute instructions to an intelligent and faithful assistant or nurse. The doses are to be gradually diminished in proportion as the local and general symptoms denote improvement.

The extent to which opiates are to be given in order to secure the objects

¹ *Therapeutic Gazette*, Nov. 15, 1893.

of the treatment will vary much in different cases. Other things being equal, the doses required will depend on the degree of pain; but the susceptibility of different persons to opium varies greatly, and in peritonitis, as in some other diseases, there is sometimes an extraordinary tolerance of this remedy. Thus, in one of the cases treated successfully by Prof. Alonzo Clark the patient took within the first twenty-six hours, of opium and the sulphate of morphia, a quantity equivalent to 106 grains of opium; in the second twenty-four hours she took 472 grains; on the third day, 236 grains; on the fourth day, 120 grains; on the fifth day, 54 grains; on the sixth day, 22 grains; and on the seventh day, 8 grains, after which the treatment was suspended. This patient, Prof. Clark had reason to believe, was not accustomed to the use of opium in health, and was not intemperate. As regards the amount of opium required, this case is exceptional, the patient having an enormously increased tolerance of this drug. Rarely is more than half a grain of a salt of morphia every two, three, or four hours needed. Often the requisite effects are produced by smaller doses. If there be irritability of the stomach, the opiate should be given by hypodermic injections. Vomiting conflicts with the great object for which opiates are given—namely, rest of the inflamed part, and therefore everything is to be avoided which will be likely to excite it.

In the TREATMENT of this disease the main reliance is upon opiates; but other measures are important. Quietude of the body is to be enjoined, and the bladder is to be relieved by the timely use of the catheter if there be retention of urine. Rubefacients, sinapisms, or turpentine stupes may be applied over the abdomen. Blisters are contraindicated. All the good to be done in the way of revulsion will be effected by rubefacients, and counter-irritation beyond this does harm by increasing constitutional disturbance and contributing to depress the powers of life. Warm fomentations to the abdomen, if grateful to the patient, are useful; poultices are uncomfortable from their weight, and the water-dressing or the spongio-piline is to be preferred. I cannot speak of the utility of cold applications from much observation, but it is safe to trust to the feelings of the patient in deciding between cold and warm applications. Cold may be applied by means of compresses dipped in ice-water and renewed at intervals of a few minutes, or the ice-bag. Sustaining measures are indicated in proportion as the symptoms denote failure of the vital powers. Alcoholic stimulants and concentrated nourishment constitute the supporting measures which are not less appropriate to this disease than to other diseases tending to destroy life by asthenia. I have seen cases in which life apparently was saved by the free and persevering use of alcoholic stimulants in conjunction with the use of opiates. The employment of cathartics in convalescence calls for great circumspection; and they may not be required, the bowels acting spontaneously. The liberal use of opiates continued throughout the disease does not appear to conduce to constipation, and it does not prevent the occurrence of diarrhoea in a certain proportion of cases. Quinia in full doses as an antipyretic remedy is indicated if there be hyperpyrexia.

As an addendum to the treatment of this disease may be offered a suggestion relating to measures which doubtless are too bold to commend themselves without having been carefully considered. These measures are, making an opening through the abdominal wall, washing out the peritoneal cavity by injecting a tepid disinfecting liquid, and maintaining the opening so as to secure effectual drainage. These measures of course are applicable only to cases in which the presence of septic, infective morbid products may be inferred. In many instances these products probably constitute the chief

source of danger. Modern experience in ovariectomy and in the operation of laparotomy in cases of intestinal obstruction has shown the admirable results which follow cleansing of the peritoneal surfaces, and the absence of the great danger formerly attributed to laying open the abdominal cavity. The time may come when paracentesis abdominalis for the purposes just stated will have been proved to be as applicable to certain cases of peritonitis as are thoracentesis, injections into the pleural cavity, and a permanent opening in the chest to cases of suppurative pleurisy.

The foregoing paragraph was contained in the last edition of this work, published in 1881. Since that date several cases have been reported in which the abdomen was opened, the purulent contents washed out, and antiseptic injections employed. Dr. Z. B. Adams reported a case for the *Boston Medical and Surgical Journal*, Nov. 20, 1884, in which this practice was successfully pursued. A successful case has been reported to me in a letter by Dr. Eug. A. Crouse of Iowa. Leyden and others in Germany advocate the treatment of suppurative peritonitis after the manner of empyema, and illustrative cases are cited.¹

Circumscribed Peritonitis.

Inflammation limited to a circumscribed portion of the peritoneum is almost invariably a complication of a prior affection of the parts covered by the inflamed portion of the membrane. Circumscribed peritonitis may be acute or chronic, but these varieties cannot be sharply separated from each other. When inflammation reaches the surface of an organ covered by peritoneum the latter always becomes inflamed. Hence, a local peritonitis is frequent in various lesions of the stomach, intestine, liver, gall-bladder, spleen, urinary bladder, and the uterus and its appendages. Ulceration of the stomach leads to a peritonitis limited to the site of the ulcer. Cirrhosis of the liver in the great majority of cases is accompanied by inflammation of the serous investment of this organ. This inflammation is called perihepatitis. It leads to thickening of the hepatic capsule and to the formation of adhesions with the diaphragm and other adjoining parts. A similar perihepatitis often accompanies abscess, cancer, and some other affections of the liver. Perisplenitis signifies a local peritonitis about the spleen and is not infrequently found at post-mortem examinations. Among the most frequent and important forms of circumscribed peritonitis is inflammation of the pelvic peritoneum in females—pelvic peritonitis, perimetritis, peri-oöphoritis. Intestinal ulcers and typhlitis often lead to circumscribed peritonitis. In consequence of adhesions a perforation of the intestinal canal may give rise to only partial peritonitis. Encysted collections of pus may be present in the peritoneal cavity, without diffuse peritonitis. Diaphragmatic pleuritis may be accompanied by inflammation of the adjacent peritoneum.

The inflammatory products in circumscribed peritonitis are the same as in the diffuse form. The exudation in many instances is chiefly fibrinous. In some chronic cases resulting in formation of new connective tissue it is probable that from the onset there is simply a new growth of connective tissue without any free exudation. The perihepatitis accompanying cirrhosis of the liver is usually of this simple proliferative form. The peritoneal thickening and fibrous adhesions which result from circumscribed peritonitis may cause displacements and deformities of the viscera. Displacements of the uterus and of the ovaries thus induced are frequently met with in gynecological practice. Circumscribed hemorrhagic peritonitis will be considered in the following article.

¹Vide *Verhandlungen des Vereins für innere Medicin zu Berlin*, 1884; also, *Am. Journ. of Med. Sciences*, April, 1885, p. 573.

The SYMPTOMS of circumscribed peritonitis are pain and tenderness within a space corresponding to the extent of the inflammation, accompanied perhaps by more or less febrile movement. These symptoms are marked in proportion to the acuteness of the inflammation, but circumscribed peritonitis is oftener subacute or chronic than acute. Physical exploration in some cases furnishes diagnostic evidence. The presence of fibrin may occasion a friction sound or a tactile sensation of rubbing due to the attrition of opposed surfaces by the diaphragmatic respiratory movements. This sign is most likely to be obtained when the peritonitis is situated over the liver and spleen. It is obtained in cases of circumscribed oftener than of diffuse peritonitis, and is of comparatively less importance in the latter, because the symptoms generally suffice for the diagnosis if the inflammation be diffuse.

It must be difficult, if not impossible, to determine the existence of circumscribed peritonitis not connected with an affection of the parts covered by the inflamed portion of peritoneum. Cases, however, are so rare that, the existence of circumscribed peritonitis being ascertained, an affection of the part covered by the inflamed membrane is to be inferred.

The PROGNOSIS in cases of circumscribed peritonitis will depend on the nature and extent of the affection of which the peritonitis is a complication. The adhesions resulting from the inflammation may be either conservative or deleterious.

So far as the peritonitis is concerned, palliative treatment is alone called for.

Chronic Peritonitis.

Chronic peritonitis may be of the following varieties: 1, with exudation of serum, fibrin, and pus, as in acute peritonitis; 2, chronic serous peritonitis; 3, peritonitis with predominant production of connective tissue; 4, hemorrhagic; 5, tuberculous; 6, cancerous.

Chronic peritonitis with exudation of serum, fibrin, and pus may follow an acute peritonitis or may develop slowly and insidiously. It is more frequent as the sequel of an acute peritonitis than in a latent form, but it is in either case a rare variety of the disease. There is sometimes, but not always, coincident disease of some of the abdominal viscera. In consequence of the formation of membranous adhesions the fluid part of the exudation often becomes sacculated. Sometimes the exudation consists almost wholly of fibrin, by which the intestines and other viscera may be agglutinated to each other and to the parietal peritoneum. The intestinal walls are softened and easily torn. Chronic peritonitis with an exudation almost wholly purulent sometimes develops insidiously. When acute peritonitis passes into a chronic state the pain, tenderness, and tympanites diminish, but they do not wholly disappear. There are usually recurring febrile paroxysms with intervals of apyrexia. Gastric and intestinal disorders are present. The patient is troubled more or less by vomiting. The bowels are irregular, constipation alternating with diarrhoea. The patient emaciates and becomes anæmic. Sometimes irregularities due to encysted collections of fluid in the peritoneal cavity may be made out by inspection, palpation, and percussion. When the disease begins insidiously it is usually not susceptible of diagnosis. The prognosis is unfavorable, but recovery may take place by absorption and by the formation of adhesions. Collections of pus may ulcerate and escape into the bowels or externally.

Chronic serous peritonitis is usually secondary to ascites. Together with the accumulation of a large amount of serous fluid in the peritoneal cavity there are evidences of inflammation. The serous fluid may be rendered somewhat turbid by the admixture of pus-cells. In some cases there is fibrinous

exudation upon the peritoneal surface; and in others the chronic inflammation is manifested by fibrous thickening of the peritoneum, either diffuse or in the form of nodules. The nodules may resemble tubercles in their gross appearance. These various appearances may be combined. Peritonitis is not a frequent complication of ascites. It is more likely to develop after repeated tapings than when paracentesis has not been performed. In very rare instances chronic serous peritonitis is an idiopathic affection. Cases of this nature were formerly described as idiopathic dropsy of the peritoneum, but it is probably more correct to regard them as inflammatory in origin. A serous fluid accumulates, as in ascites; but none of the recognized causes of ascites are present, such as obstruction of the circulation in the liver, in the lungs, or in the heart, or as Bright's disease, hydræmia, tuberculosis, or cancer. In most cases there is either a free inflammatory exudation or a formation of new connective tissue in the peritoneum; but there is sometimes no more sign of inflammation than in an ordinary case of ascites.¹ Peritonitis complicating ascites may be suspected when the symptoms of the former disease, which have been described, develop; but it rarely happens that these symptoms are manifested with sufficient intensity to be diagnostic. It is very difficult to distinguish idiopathic chronic serous peritonitis, on the one hand, from ascites, and, on the other hand, from tuberculous peritonitis. This difficulty is increased by the rarity of the disease, which in a given case raises a strong presumption against its existence. A probable diagnosis can be reached only by excluding the symptoms and causes of the two diseases in question. In ascites due to that large group of causes occasioning obstruction to the circulation the spleen is almost invariably enlarged, while in the disease under consideration this organ is not affected. Serous peritonitis may occur in chronic alcoholism, as pointed out by Leudet.²

Peritonitis with predominant production of connective tissue may be called *proliferative peritonitis*. The new connective tissue is in the form either of adhesions or of thickening of the peritoneum. The two alterations may be combined. This form of chronic peritonitis may develop without any production of fibrin or of pus, or a moderate amount of these products may be present. Proliferative peritonitis with adhesions as the chief lesion is generally circumscribed. This has been mentioned in the preceding article. Peritonitis with fibrous thickening of the peritoneum is sometimes observed in connection with cirrhosis of the stomach. The serous covering of the stomach and intestine, the omentum, the mesentery, and the mesocolon are sometimes enormously thickened by the production of fibrous connective tissue. The peritoneum in other situations may also be thickened. The omentum, mesentery, and mesocolon are usually retracted. The coils of intestine may be inextricably united to each other by the new growth of tissue. Not only is the cavity of the stomach encroached upon, but the lumen of the intestine may also be diminished. There is usually serous or sero-purulent liquid in the peritoneal cavity, and there may be fibrin upon the thickened peritoneum. Chronic inflammation of the gastro-intestinal mucous membrane is generally present. This form of peritonitis is comparable to the chronic interstitial inflammation of parenchymatous organs. The symptoms point to some severe abdominal trouble. The symptoms of chronic gastro-enteric inflammation are often present. Vomiting, diarrhœa, dull pain, and emaciation may be mentioned as frequent symptoms. The distinction often cannot be made from

¹ In ascites the peritoneum is often thickened, and even when no changes are visible to the naked eye it is not perfectly normal. The endothelial cells are changed in size and in shape, and present evidences of proliferation (Delafield). Similar changes exist in the pleura in hydrothorax and in the tunica vaginalis testis in hydrocele.

tuberculous peritonitis or from cancer of some of the abdominal organs. The same induration of the peritoneum and of the abdominal organs which may be felt through the abdominal walls is often present in tuberculous peritonitis.

Hæmorrhagic peritonitis may be either diffuse or circumscribed. Reference is not had in this connection to a simple staining of the inflammatory products with blood, such as often occurs in cancerous and tuberculous peritonitis, but to a special form of inflammation characterized by the development, upon the peritoneum, of successive thin layers of connective tissue, rich in wide capillaries with thin walls, which readily rupture and give rise to large and small hæmorrhages. The new membrane is reddish or brown in color, from infiltration with blood. Extensive extravasations of blood form hæmatomata. This peculiar form of peritonitis is analogous to chronic hæmorrhagic pachymeningitis, which will be described in the next section of this work. Fricke has observed two cases of diffuse hæmorrhagic peritonitis in patients with ascites who had been repeatedly tapped. The circumscribed form was first described by Virchow. It is met with especially in the recto-uterine fossa where it causes bloody tumors known as retro-uterine or pelvic hæmatocel. A similar hæmatoma may occur in the recto-vesical fossa in males. The prognosis in pelvic hæmatocele is good, the blood being often absorbed with astonishing rapidity. The consideration of this form of disease belongs to works on gynæcology. There are no symptoms diagnostic of diffuse hæmorrhagic peritonitis. Cornil and Ranvier mention the occurrence both of diffuse and of circumscribed hæmorrhagic peritonitis in hypertrophic cirrhosis, in articular rheumatism, in tuberculosis, and in Bright's disease. It is a form of inflammation.

Tuberculous peritonitis, of all the forms of chronic diffuse peritonitis, is the most common and of the greatest clinical importance. In acute miliary tuberculosis the peritoneum, especially the omentum and the serous covering of the liver and of the spleen, is studded with small, gray miliary tubercles. This acute tuberculosis of the peritoneum is accompanied usually by little or no serous effusion. It is not attended by recognizable symptoms, and is not included under the heading of tuberculous peritonitis. So, too, the eruption of miliary tubercles, combined often with local inflammation, on the peritoneum, covering the site of tuberculous ulcers of the intestine, is of pathological rather than of clinical interest.

The most frequent form of tuberculous peritonitis is characterized by abundant production of firm connective tissue. This new tissue causes thickening of the serous membrane and intimate adhesion of coils of intestine and other abdominal organs to each other and to the abdominal walls. The intestinal coils are inextricably matted together. The omentum is drawn up into a thick, hard mass which can sometimes be felt during life as a transverse band above the umbilicus. The mesentery and mesocolon are likewise thickened and retracted. Tubercles are present everywhere in the thickened peritoneum and in the adhesions. They appear as translucent miliary granulations, as yellow caseous deposits, and as fibroid nodules. Some fibrinous exudation is present. Cases differ much as to the quantity and the character of the effused liquid. The quantity may be small, but more frequently it is abundant, so that during life hydro-peritoneum is simulated. In the majority of cases the liquid consists of turbid, blood-stained serum. A hæmorrhagic effusion is common in tuberculous inflammation of all serous membranes. Fresh ecchymoses and old pigment-stains are often present in the fibrous tissue, especially near the tubercles. The fluid part of the exudation is frequently shut into separate cavities by means of the extensive adhesions. Encapsulated collections of pus are found not very infrequently.

These, as well as softened tubercles, may lead to ulcerations into the intestinal canal from without. The adherent coils of intestine may also ulcerate into each other. Even fecal fistulae, opening through the abdominal parietes, may be formed.

In another form of tuberculous peritonitis there are few or no adhesions; there is an abundant collection of somewhat turbid, and often bloody, serum: and the peritoneum, which may be thickened, is studded with a large number of tubercles which may coalesce into the form of nodules and plaques as much as an inch in diameter. This form has been called tuberculous ascites.

Still less frequent is a third form described by Wilks and Moxon under the name of latent peritoneal tubercle. The peritoneum is studded with tubercles in the midst of a soft, gelatinous, fibrinous exudation by which its surfaces adhere to each other.

Tuberculous peritonitis in extremely rare instances may be a local affection. It is usually accompanied by tubercles in other parts of the body. As a rule, there is pulmonary tuberculosis, but cases are not very infrequent in which the pulmonary lesions are comparatively trifling, and there may be no pulmonary tuberculosis whatever. Tuberculous pleurisy is a very frequent accompaniment of tuberculous peritonitis. Primary tuberculosis of the genito-urinary organs—in females of the uterus and Fallopian tubes, in males of the epididymis and testicle, also of the bladder, ureters, and kidneys—has been repeatedly followed by tuberculous peritonitis. The mesenteric glands, the spleen, and the liver often contain tubercles in all forms of this disease. There may be intestinal ulcers and waxy degeneration of various organs. Cirrhosis of the liver has been repeatedly observed associated with chronic tuberculous peritonitis. Tuberculous peritonitis may occur at any age. It is rarer before the fourth and after the fortieth year of age than at other periods.

As regards clinical history and diagnosis, tuberculous peritonitis is an obscure disease. It may begin acutely or may be attended by acute exacerbations, but as a rule it is insidious in its onset and slowly progressive in its course. There is usually moderate fever, with more or less acceleration of the pulse. Vomiting and other digestive disturbances are more or less prominent. Diarrhoea alternates with constipation. Other general symptoms are—night-sweats, hectic paroxysms, progressive emaciation, anæmia, and general debility. As regards local symptoms, abdominal pain and tenderness may be wanting, and they rarely are prominent symptoms. Increasing distension of the abdomen by fluid and by meteorism may be the first symptom to attract attention. It may be possible to make out encysted collections of fluid in the abdomen and tumors formed by agglutinated coils of intestine. The detection of the thickened and retracted omentum is a significant sign.

The DIAGNOSIS of tuberculous peritonitis is not easy. When there is a large accumulation of fluid the differentiation from ascites is difficult. In the diagnosis the following points are in favor of tuberculous peritonitis: the presence of tubercles in the lungs and in other organs; the simultaneous occurrence of pleurisy; no notable decrease in the size of the liver; no enlargement of the spleen; the presence of some fever and abdominal tenderness; no history of intemperance; no marked collateral dilatation of the abdominal veins; a large quantity of albumen in the fluid; and the recognition of some of the local signs mentioned, such as the contracted omentum. The distinction of tuberculous from simple chronic peritonitis is all the more difficult from the fact that both may occur in connection with chronic pulmonary tuberculosis. In suspected cases the fluid withdrawn by tapping may be examined for tubercle bacilli, but failure to find these would not exclude tuberculous peritonitis.

The termination of tuberculous peritonitis is always fatal, either from the disease itself or from tuberculosis of the lungs or other organs. The duration is from one or two months to a year or more.

Of the tumors of the peritoneum, *carcinoma* is the only one which demands clinical consideration. The occasional occurrence of echinococcus cysts in the peritoneum may be simply mentioned. Carcinoma of the peritoneum is almost always secondary. Colloid cancer is probably the only form which develops primarily in this situation. It occurs as a diffuse growth, involving the omentum and other parts of the peritoneum. Colloid cancer has its seat by preference in the peritoneum, and it attains sometimes an enormous size, a growth weighing one hundred and fourteen pounds having been reported. Peritoneal cancer may develop as secondary to cancer of the ovary, uterus, testicle, retro-peritoneal glands, rectum and other parts of the intestine, stomach, liver, pancreas, etc. It may appear in the form of one or more large tumors in the serous membrane, or there may be countless little cancerous nodules studding the peritoneum. The latter distribution is called miliary carcinosis of the peritoneum. By the aid of the microscope it is readily distinguished from tuberculosis, which it resembles in gross appearance. Peritoneal carcinoma is not necessarily accompanied by inflammation. Usually, however, there is considerable accumulation of brown serum which may contain fibrin. The brown color comes from admixture with blood. A new growth of connective tissue, with agglutination of intestinal coils, may accompany cancer as well as tubercle of the peritoneum. In cancerous peritonitis the local symptoms do not differ materially from those in tuberculous peritonitis. Febrile movement is less constant and marked in the former, and perspiration is not so liable to occur. The age of the patient is greater than in the majority of cases of the latter. When the primary cancer is recognized, the diagnosis of cancerous peritonitis does not usually involve much difficulty. When, however, the primary growth is latent the diagnosis is not easy. The recognition of tumors seated in the peritoneum is of assistance in diagnosis. The examination of the fluid withdrawn by tapping may also be of assistance. It has been pointed out by Foulis and by Thornton¹ that in cancer of the peritoneum or in cancer of the ovary, with ascites, the fluid in the peritoneal cavity often contains large cells in groups (budding cells, group-cells). The prognosis is fatal.

As regards the TREATMENT of the different varieties of chronic peritonitis, the objects are, to palliate the local symptoms, and by tonic remedies, nutritious diet, and hygienic influences to enable the system to tolerate the disease as long as possible.

Hydro-peritoneum—Ascites.

The term hydro-peritoneum or ascites denotes peritoneal dropsy. The fluid accumulated in the peritoneal cavity consists of clear serum with the properties belonging to transudations in general. Like other dropsies, hydro-peritoneum is a symptom or an effect of disease, not strictly a disease in itself. It is, however, convenient and proper to give separate consideration to it as the accumulation of liquid in the peritoneal cavity may be the first chief manifestation of disease, and as it occasions inconvenience and death to which therapeutical measures are specially directed. Hydro-peritoneum may occur either as a local dropsy or as part of a general dropsy, is, in conjunction with anasarca and with dropsical accumulations in serous sacs.

¹ *British Med. Journ.*, 1878.

With very few exceptions, ascites, occurring as a local dropsy, is the result either of disease of the peritoneum or of obstruction in the main trunk of the portal vein or in the branches of this vessel within the liver. In most if not all cases in which the ascites is attributable to disease of the peritoneum the fluid accumulation is to be regarded as an inflammatory effusion rather than as a transudation. This is proven by the presence of a certain degree of inflammation in these cases, and by the fact that the fluid, in the amount of albumen which it contains, is, as a rule, more closely allied to exudations than to transudations. The inflammation is often no more than a chronic thickening of the peritoneum, either diffuse or in the form of nodules, and it may not be attended by the exudation of fibrin. This form of peritonitis has been described in the preceding article as chronic serous peritonitis. Tubercles and cancer of the peritoneum may also be causes of ascites, even when marked inflammatory changes are absent; but here, too, the serous accumulation is to be attributed to inflammatory alterations, which careful examination will usually reveal. It is a rule that slight inflammatory changes in the vascular walls are attended by an effusion chiefly serous. Obstruction of the main trunk of the portal vein, as a result of thrombosis or pylephlebitis, in most cases is followed by ascites. Cirrhosis is the most common morbid condition, seated in the liver, which causes ascites. Syphilitic hepatitis is also a cause of ascites. Echinococcus, abscess, cancer, and other tumors of the liver may cause ascites by compressing the portal vein or its principal branches. Atrophy of the liver induced by external pressure or by growths in its substance may likewise be a cause. Advanced amyloid degeneration of the liver is accompanied by ascites as a rule. These various diseases of the liver will be considered in the following chapters. With the possible exception of amyloid liver, they all cause ascites by interfering with the portal circulation through this organ.

The causes of hydro-peritoneum in conjunction with general dropsy are obstruction to the circulation in the lungs and through the heart and a hydræmic state of the blood. The most important of the pulmonary causes are emphysema and fibroid induration and contraction of the lungs, such as may follow chronic pleurisy. Uncompensated valvular lesions and other organic diseases of the heart are frequent causes of ascites with general dropsy. Bright's disease is by far the most important cause of ascites referable to hydræmia; but other cachexiæ, as the tuberculous, the cancerous, the syphilitic, and the malarial, may also cause hydræmic dropsy. From the foregoing it is evident that dropsy of the peritoneum, as of other parts, may be divided into mechanical dropsy and cachectic dropsy. Ascites due to mechanical causes (obstructions to the circulation in the liver, lungs, or heart) reaches a higher degree than that due to hydræmia.

Ascitic fluid consists, as a rule, of yellowish serum. In cachectic peritoneal dropsy it is clear and watery in appearance. In cirrhosis of the liver it is darker in color. It may be stained with blood, especially in tuberculosis and in cancer of the peritoneum. The specific gravity is rarely below 1004 and seldom exceeds 1020. The percentage of albumen is less than in exudations. In dropsical accumulations in the peritoneal cavity the quantity of albumen is usually less than 2½ per cent., whereas in inflammatory exudations in the same situations the quantity generally exceeds 4 per cent. In cachectic ascites the amount of albumen rarely exceeds 1 per cent., whereas in ascites due to tuberculosis of the peritoneum the quantity is, as a rule, greater than 2½ per cent. Chemical examination of fluid removed by tapping may thus be of assistance in diagnosis. Ascitic fluid contains fibrinogen, and it often coagulates spontaneously when withdrawn from the body. At autopsies ascitic fluid is by no means always found devoid of coagulated

fibrin. Since Schmidt's investigations as to the coagulation of fibrin it has not been found possible to draw as sharp a distinction between fluids free from fibrin and those containing this substance as was formerly done.

The transudation may present a milky appearance from an admixture of chyle in consequence of compression or of rupture of the thoracic duct or large chyle-vessels. This condition is called chylous ascites (*hydrops chylusus*.) A similar appearance may be due to the presence of a large number of fat-granules and of cells containing molecules of fat. This constitutes *hydrops adiposus*. It has been observed in connection with cancer and with tubercle of the peritoneum. In one case of chylous ascites which followed residence in a tropical climate Winckel found in the fluid countless parasites resembling the *Filaria sanguinis* detected by Lewis in the blood of those suffering from chyluria.¹

In the account of the clinical history of ascites reference is not had to slighter transudations, such as occur in cachectic states, and which, as a rule, neither give rise to symptoms nor call for therapeutical interference.

The effusion of liquid and its accumulation take place without pain, tenderness, or any local subjective symptoms. The enlargement first directs attention to the abdomen. In the majority of cases it goes on with rapidity, and the abdomen soon becomes considerably or greatly distended. The symptoms referable directly to the dropsy proceed from the mechanical pressure of the liquid and are in proportion to the quantity of the effusion. The distension of the abdominal walls by the liquid and its weight occasion more or less inconvenience. The functions of the abdominal organs (stomach, liver, kidneys) are impaired by compression. Pressure on the veins within the abdomen gives rise to oedema in the lower extremities. The movements of the diaphragm are restrained or arrested, breathing being carried on by the costal muscles, and if the accumulation be very large the capacity of the chest is diminished by the upward pressure. The appetite is usually impaired. A sense of fullness is frequently felt after taking food in moderate quantity. Vomiting and diarrhoea are occasional symptoms.²

Enlargement of the superficial veins on the anterior aspect of the trunk is a consequence of the passage of a portion of the blood from the portal vein into the systemic venous system through anastomosing branches. The superficial veins of the abdomen in some cases, of the chest in other cases, and sometimes in both situations, become more or less dilated, presenting a varicose appearance. Hernial protrusions at the umbilicus and in other situations are occasionally produced.

When the fluid accumulation is considerable, oedema of the lower extremities is a pretty constant symptom, the amount of oedema varying much in different cases. The limbs, scrotum, and penis sometimes become enormously swollen. Some oedema of the lower limbs preceded an enlargement of the abdomen sufficient to attract the attention of the patient in one-half of the cases (21) among those analyzed by me, the histories of which contained information on this point. Oedema of the face and upper extremities does not belong to the clinical history of local hydro-peritoneum. If present, it usually denotes coexisting renal or cardiac disease. In the progress of the affection emaciation and pallor become marked. The attenuation of the upper part of the body, the distended abdomen, and the oedematous lower extremities combine to render the appearance highly characteristic of the

fection. Cholaemia or icterus is occasionally present. It occurred in 7 of the 46 cases which I have analyzed.

Fever does not attend the progress of this affection. The pulse may be more or less increased in frequency and proportionately feeble, or it is more or less enfeebled without acceleration. The urine is frequently scanty. The mind is usually intact, but in a certain proportion of cases, toward the close of life, delirium, convulsions, and coma occur. These symptoms may be due to uraemia or to retention in the blood of the excrementitious principles of the bile (cholesteræmia).

The mode of dying in the great majority of cases is by slow asthenia. A rapid and large accumulation of liquid may destroy life by interference with respiration; and apnoea and asthenia are combined when coma precedes death.

The PROGNOSIS in most cases is unfavorable. The cases in which a permanent recovery takes place are few. The morbid conditions on which the affection is dependent are generally incurable, and lead to its return, sooner or later, in most of the cases in which the dropsy disappears or is removed. The duration of the affection is variable. In the fatal cases of those which I have analyzed, the duration varied between six weeks and seventeen months, the average duration being more than five months. Cases in which the affection is attributable to obstruction of the portal vein by non-infecting emboli or by thrombi may end in recovery, changes in the obstructing thrombus or embolus taking place which permit return of circulation through the obstructed vessel. Instances apparently exemplifying this fact have come under my observation.

The DIAGNOSIS of hydro-peritoneum is generally made without difficulty, yet there is a liability to errors which may lead to serious results. A distended bladder has been punctured, the case being supposed to be one of peritoneal dropsy. There is a tradition that John Hunter made this mistake. On careful examination the tumor formed by the distended bladder may generally be felt through the abdominal walls, but the introduction of the catheter is the diagnostic test. The sacculated bladder may cause a notable anterior projection of the abdomen. The contents of the saccular appendage may generally be removed by the catheter combined with suction by means of an india-rubber bag. Pregnancy, the liquor amnii being unusually abundant, has been mistaken for dropsy and the uterus has been punctured. Careful examination through the abdominal walls and *per vaginam*, together with auscultation of the abdomen, should prevent this error. Great corpulence has led to error and to the operation of paracentesis, as in the famous case of "dry tapping" related in the lectures of Sir Astley Cooper. Finally, tympanites, large abdominal tumors, and ovarian cysts are to be discriminated from peritoneal dropsy.

The enlargement of the abdomen from dropsy begins at the lower part; and if the abdomen be not largely distended it is more marked below than above when the patient stands or sits. The enlargement on both sides is equal, and the abdomen is symmetrical. If the patient lie upon either side, the weight of the liquid causes the depending side to sag. Percussion on one side, the open palm being placed on the opposite side, frequently causes a characteristic shock, called the sense of fluctuation. Sometimes this sensation is more appreciable when the palm is placed near the point at which the percussion is made. The former method of percussion gives rise to what is called diametrical, and the latter to peripheral fluctuation; but a more satisfactory application of percussion is to compare the results when the patient is placed in different positions. Percussing first in the sitting or standing posture, tympanitic resonance, from intestinal gas contained in the intestine

floating upon the liquid, is usually found at the upper part of the abdomen, extending below for a greater or less distance, and flatness from this point to the pubis. Placing the patient on the back, the change in the relative situation of the liquid and the intestine is shown by the greater extension of the tympanitic resonance toward the pubis. Similar proof of the presence of liquid is obtained by percussing upon either side of the abdomen successively, the body being inclined first to one side, and then to the other. The exceptional cases in which this test afforded by percussion is not available are those in which the intestinal coils are fixed by morbid adhesions. This is rare in cases of a purely dropsical affection.

The several affections simulating dropsy which have been named may generally be excluded by the application of percussion as just described. Ovarian cysts of sufficient size to distend the whole abdomen are the most likely to be confounded with hydro-peritoneum. These are generally, however, distinguishable by the appreciation of the form of the cyst through the abdominal walls, the existence of a tumor on one side before it extended to the whole of the abdomen, the absence of symmetry in the enlargement of the two sides, together with the want of evidence of the presence of liquid in the peritoneal sac, afforded by percussion when the body is placed in different positions. The chemical and the microscopical examination of the fluid removed by puncture often assists in this differential diagnosis. When the fluid is thick and viscid it is ovarian. The thin ovarian fluids present more difficulty in diagnosis. The presence of a large quantity of a modified form of albumen, called paralbumen, is diagnostic of ovarian cysts. So, too, the recognition of a large number of granular corpuscles devoid of nuclei, in which the granules are insoluble in acetic acid and in ether, is diagnostic. These bodies are known as the ovarian corpuscles of Drysdale. The detection of a few of these corpuscles and the presence of a small quantity of paralbumen are not sufficient for the diagnosis. Ovarian fluids very rarely coagulate spontaneously. If cylindrical epithelial cells be found, the fluid comes from an ovarian cyst, but these cells are rarely discovered. The specific gravity of ovarian fluids is generally higher than that of ascitic.
